Table I. Test Circuits for the Measurement of Capacitance and Power Factor of 2-Conductor Metallic-Sheathed Cable

Connection Designation	Voltage High to Low	Capacitance and Dissipation Factor Readings	Test Circuit
AA	1/2 operating	$2C_a$ DF_a	C_{12}	operating	C_{12} DF_{12}	AA'	operating	$2C_a'$ DF_a'	
CA	operating	C_{ca} DF_{ca}	CB	operating	C_{cb} DF_{cb}	
circuit, then use circuits AA', CA, and CB.

Using circuit AA'

$2C_a' = 0.2032$ microfarad
$DF_a' = 0.6695$ per cent

Using circuit CB

$C_{cb} = 0.1084$ microfarad
$DF_{cb} = 0.666$ per cent

Using circuit CA

$C_{ca} = 0.1084$ microfarad
$DF_{ca} = 0.672$ per cent

Average the results of circuits CA and CB

$C_c = 0.1084$ microfarad
$DF_c = 0.669$ per cent

Now use equation 16

$$C_{12} = C_c - C_a' = 0.1084 - 0.1016 = 0.0068 \text{ microfarad}$$

And equation 17

$$DF_{12} = \frac{C_c DF_c - C_a' DF_a'}{C_c - C_a'} = \frac{0.1084 \times 0.669 - 0.1016 \times 0.6695}{0.1084 - 0.1016} = 0.662 \text{ per cent}$$

Having C_{12} and DF_{12} use equations 14 and 15 as previously. The two methods are found to agree within better than 1 per cent.

Appendix IV. Derivation of Equivalent Circuit of a 2-Conductor Metallic-Sheathed Cable

Figure 5 shows the cable section with its component interadmittances. Equivalent electric circuit is shown in Figure 6(A).

Assuming perfect cable symmetry, $C_a = C_b$; $g_a = g_b$.

Figure 6(A) then readily reduces to 6(B)

$$g = \frac{g_a}{2} + g_{12}$$

$$C = \frac{C_a}{2} + C_{12}$$

$$\tan\phi = \frac{g}{wC} = \frac{g_a + 2g_{12}}{w(C_a + 2C_{12})} = \frac{C_a \tan\phi_a + 2C_{12}\tan\phi_1}{C_a + 2C_{12}} \quad (18)$$

Since $\tan\phi = PF$ for values under 0.10 and using the designation, DF, for $\tan\phi$, we have

$$PF = \frac{C_a DF_a + 2C_{12} DF_{12}}{C_a + 2C_{12}} \quad (19)$$

Discussion

Wm. A. Del Mar (Phelps Dodge Copper Products Corp., Yonkers, N. Y.): One cannot help wondering why Mr. Greenfield is resurrecting that relic of bygone days, the belted cable and reviving, as something new, the single-phase method of testing it, which was abandoned long before the belted cable itself passed into oblivion.

The single-phase method gives low power factors, as compared with the 3-phase method because it neglects losses due to tangential stresses.

Another error is introduced by the artificial voltage relations, because when one conductor is tested against two conductors, the voltage between the one conductor and ground is much greater than that between the pair and ground due to the capacitance effect.

Tests were made on a 15 foot length of belted cable (12/64 by 6/64) by setting a spark-gap between conductor and sheath and noting the voltage applied between conductors when the spark-gap flashed. It was found that when one conductor was connected to the high-tension terminal of the transformers, the voltage between sheath and the one conductor was twice that between sheath and the two conductors.

When the single conductor was grounded and the pair connected to the transformer, the voltage relation became 61 to 39 instead of 2 to 1.

W. B. Kouwenhoven (The Johns Hopkins University, Baltimore, Md.): Dr. Greenfield has presented a clear analysis of the 3-phase power cable loss problem, and has provided a tool for the determination of the 3-phase loss by single-phase measurement technique.

I would like to know if there is much difference in the results when the measurements are taken between conductor 1 and conductor 2–3, between 2 and 1–3, and between 3 and 2–1.

I also would like to know if any measurements have been made that will give the magnitude of the loss in the insulation which is caused by the rotating electrostatic field set up by the 3-phase voltages.

E. W. Greenfield: Mr. Del Mar is apparently under the impression that I have "resurrected that relic of bygone days, the belted cable . . .". Mr. Del Mar, being in the cable manufacturing business, should well know that the belted cable has not "passed into oblivion." There are many miles of belted cable in various moderate voltage operating systems with long-time successful records. Occasional replacements and system expansion have always and do now provide a sizeable proportion of paper cable orders.

Mr. Del Mar also accuses me of "reviving" as something new, "the 1-phase method of testing belted cables" which, he goes on to say "was abandoned long before the belted cable itself passed into oblivion." Obviously if belted cables are being manufactured today, they must be tested. The current edition of the Association of Edison Illuminating Companies' specifications as did its predecessors, provides that power factor measurements shall be made on belted cable having ratings of 8 kv or above. Either 3-phase or 1-phase methods are permitted but no details of the test method are given.

Older methods of testing belted 3-conductor cable generally involved a 3-phase scheme using a compensated wattmeter. With the advent of the Schering bridge (and others) as used first in Europe and then in this country, it was found at last, that precision phase-angle measurements were possible. In consequence the old 3-phase wattmeter methods were abandoned therefore in favor of the more accurate bridge method. Few cable manufacturers or users employ the 3-phase wattmetric method today since excellence of modern materials and assembly almost make a shielded bridge mandatory. The contribution of my paper is that it sets down, for the record, the measuring methods and formulations whereby 1-phase measurements can be converted to 3-phase measurements.

I do not know of any previously published similar material.

Mr. Del Mar states that the 1-phase method neglects losses due to tangential stresses and therefore gives values of power factor lower than that obtained by the 3-phase method. This statement does not appear to be valid since the electric field between high and low conductors in the 1-phase case meet the cable structure at angles which are the same as in the 3-phase case.

This also is true of the high conductors to the sheath.

The tests using sphere gaps, of which Mr. Del Mar speaks, appear to have to do with a "floating" conductor cable. This has little or no revelancy to the problem at hand. In the 1-phase method both the low conductors and the sheath are always at or practically at ground potential. To summarize, the 1-phase method, by selecting proper voltages and bridge connections, can employ the principle of superposition to add up the losses in the variously stressed portions of the cable structure and give a net result practically equivalent to that obtaining in a 3-phase system.

Prof. Kouwenhoven asks what differences in power factor are found when measuring between the various conductors of a modern 3-conductor belted cable. The maximum difference I can find in a survey of belted cable tests extending back for several years is about 10 per cent. In most cases the differences appear to be between 2 and 6 per cent, with a possible average of 5 per cent.

A typical belted cable tested at room temperature and operating voltage has values as follows: conductor 1 versus 2 and 3; 0.7 per cent, conductor 2 versus 1 and 3; 0.72 per cent, and conductor 3 versus 1 and 2; 0.69 per cent.

With regard to the 3-phase field in such a cable, this much can be said: With 3-phase voltage applied, each conductor attains one positive maximum, and one negative maximum potential with respect to the sheath per cycle. Therefore in any one cycle the insulation between each conductor and sheath is under maximum stress twice per cycle. Also, each conductor attains two maximum differences of potential with respect to the other conductors per cycle, making a total of six maximum differences of potential between conductors per cycle. Hence the three insulation paths between conductors are each under maximum stress twice per cycle. Further, during the instant of maximum potential difference between conductors, two of them are at exactly the same voltage with respect to sheath. In the 1-phase methods described, the insulation

paths between conductors and sheath are each stressed to the same maximum value twice per cycle as is the insulation paths between conductors. Therefore, as far as maximum ionizing stresses are concerned, the 1-phase test method duplicates conditions under 3-phase operation.

The net ionizing time per cycle also is important in assessing dielectric losses. This may be loosely defined as the product of stress and time per cycle for a given pair of conductors. When the 3-phase case and the 1-phase method are analyzed on this basis the net ionizing time for both turns out to be the same.

A New High-Accuracy Counter-Type Tachometer

T. M. BERRY
ASSOCIATE AIEE

C. L. BEATTIE
NONMEMBER AIEE

Synopsis: Recent advancements in highly efficient power machinery have created demands for super accurate speed measurements. Developments in magnetic recording and high-speed electronic counters have made extremely accurate speed measurements possible. A tachometer, accurate to better than ±0.03 per cent, is described in this paper.

ALTHOUGH rotational speed measurements have been made for many years, it has not been until recently that accuracies within 1 per cent and better have been required. The 1 per cent point is approximately the ultimate accuracy for simple tachometers and is, therefore, the point where special means must be employed for higher accuracies. Simple tachometers employ such principles as the magnetic drag cup as is used in automobile speedometers, the liquid column supported by a rotary pump, and the flashing light on a rotating disk with alternate black and white sections.

This tachometer consists of three units. A pulse generator, Figure 3, is driven by the rotating machine and feeds into the electronic counting unit. The counting unit controls the remote indicator, Figure 1. When photographed, the speed indication was 15,081 rpm as shown in direct numerical form. The indicator can be read from distances up to 30 feet.

The special means used in this precision tachometer is the counting of electrical pulses from a special high-frequency generator for a precise period of time. The generator frequency and counting period are arranged so that the total count is equal to the speed in revolutions per minute. The total count is used to control the illumination of the proper number stencils whose images are presented on an opal glass screen. Although the accuracy of this tachometer is within 0.03 per cent, it can be modified so that its accuracy is much greater. A feature of the tachometer which actually limits its accuracy is that it averages the speed over a period of time instead of giving an instantaneous value.

The system does not count partial pulse periods from the generator and these pulses are not synchronized with the counting period. Because of this, a complete pulse may be included in the counting period when only part of the corresponding pulse period was included. This action occurs when the counting period starts immediately before a pulse occurs and closes immediately after the last pulse occurs. In this way, it is possible for one too many pulses to be counted. Similarly, if the counting period starts just after a pulse occurs and ends just before a pulse occurs, one too few pulses would be counted. This variation of one pulse corresponds to a variation of 0.1 rpm in speed indication for speeds up to 4,000 rpm and a variation of 1.0 rpm for speeds between 4,000 and the designed speed of 15,000 rpm. The timing element is a precision tuning fork accurate to 0.002 per cent.

Besides being inherently accurate, the system is such that frequent calibration is not necessary, and the human element is essentially eliminated because the operator has only to read or copy the indicated number instead of interpolating between divisions of a calibrated scale. Furthermore, an electric typewriter unit or other printer may be coupled to the system which will record the speed automatically.

Applications and proposed applications of the counter-type tachometer will illustrate the need for high accuracy speed measurements. In steam and gas turbine design and development, accurate speed measurement is of primary importance in the determination of efficiency. It has been found that, in testing duplicate designs over a period of time, there occurs a standard deviation in efficiency which is attributed to deviations in test equipment and the human element in taking readings. These turbines are highly developed, and often the expected improvement in efficiency, as a result of a design change, is about equal to this standard deviation. To detect changes in efficiency of 1 per cent or less, all test equipment should be accurate to 0.1 per cent or better.

A second application requiring extreme accuracy is the development testing of refrigerator compressor motors. The requirements are for an instrument which requires no calibration or zero setting, has no operator errors, and is accurate to within 2 rpm at 1,800 rpm and below, and to within 0.1 per cent of reading at speeds above 1,800 rpm. Hermetic refrigerator motors operate at such levels of efficiency that the per-cent error in motor losses is about double the per-cent error in the speed reading.

A third application for this type of tachometer is in the testing of governors for paper and textile mills where accuracies of speed control within 0.01 per cent may be required.

Operation

The operation of the unit may be described with the aid of Figure 2. At the beginning of each one second counting cycle a control voltage from the timing counter opens the electronic gate. Pulses flow from the pickup through the shaper and gate to the pulse counter where they are counted electronically. After 0.8

Paper 50-109, recommended by the AIEE Instruments and Measurements Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE North Eastern District Meeting, Providence, R. I., April 26–28, 1950. Manuscript submitted November 10, 1949; made available for printing February 27, 1950.

T. M. Berry and C. L. Beattie are both with the General Electric Company, Schenectady, N. Y.

Figure 1 (left). Remote indicator of tachometer in use

Figure 3 (right). Pulse generator cover removed

second has elapsed, the timing counter closes the gate and operates the reset relay through the power tube. The reset relay is energized for 0.1 second during which time the relay unit is released from its previous count and allowed to make any changes detected by the counter-position senser. When the reset relay is de-energized, it locks the relay unit and operates the counter resetter which resets the pulse counter to zero. The relay unit transforms the total count of the pulse counter to a speed indication by connecting power to the proper indicator lamps which illuminate number stencils. The above completes one cycle. At the 1-second point, the gate opens again and another cycle begins. The indicator indication remains fixed during each counting period. The variations of the control voltages from the timing counter for a 1.0-second cycle are shown by the square waves on Figure 2.

Pulse-Generator

Any form of pulse generator may be used which can develop an exact number of pulses per revolution. A photoelectric type was considered but the permanent magnet a-c generator was chosen for its simplicity and ruggedness. A photoelectric type would be used if no torque were available from the machine whose speed is to be measured. The rotor of the generator, as shown in Figure 3, consists of an aluminum alloy disk with magnetic wire wound on its periphery. With the rotor turning in its own bearings, the wire was ground smooth. Two stationary magnetic pickups are mounted above individual tracks of the magnetic surface.

To accommodate the speed range, maintain the required accuracy of 0.05 per cent, and keep the signal frequency within practical limits, it was necessary to divide the speed range into two sections; 400 rpm to 4,000 rpm, and 4,000 rpm to 15,000 rpm. At 400 rpm, the accuracy required is 0.2 rpm. Therefore, it was necessary to indicate speed to tenths of a revolution per minute. At 4,000 rpm, the required accuracy is down to 2 rpm, and the pickup signal frequency has reached 50 kc; so another track was made on the generator rotor with one-tenth the number of poles. The switch-over is automatic as will be described later. The number of poles in the track for the upper speed range is such that the total number of pulses counted for 0.8 second will be equal to the speed in revolutions per minute. At 4,000 rpm on the upper range, 5,000 cycles per second are generated. This signal is counted for 0.8 second so 4,000 pulses are counted. Seventy-five cycles per revolution of the rotor produces this result. On the low range, 750 cycles per revolution are used so 50,000 cycles per second are generated at 4,000 rpm. In 0.8 second, 40,000 pulses are counted with the last digit representing tenths of a revolution per minute.

The system shown schematically in Figure 4 was used to magnetize the drum. The system output is a current in the record head whose value varies sinusoidally with respect to zero as the selsyn rotor, *R-A* and *R-B*, is rotated. One cycle of current variation in the record head occurs for each revolution of the selsyn rotor. Assume *R-A* and *R-B* to be a center tapped rotor winding of the selsyn and *S* to be a stator winding whose induced voltage is equal to the voltage across half the rotor. The voltage across the rotor will remain constant but the stator voltage varies with the rotor position and reverses 180 degrees relative to the supply voltage as it goes through zero. If the rotor is rotated so that the stator voltage is maximum and points "1" of *R-A* and "2" of *S* are both positive at the same time, a maximum rectified current will flow through rectifier *D-1* and half of the recording head. No current flows through *D-2* because the voltage in *R-B* and *S* are equal and opposite.

As the rotor is turned, the stator voltage decreases to zero at 90 degrees movement and current *Y* due to voltage in *R-B* through *D-2* increases to equal current *X* which has decreased to half its initial value at zero degrees. Since currents *X* and *Y* are equal and opposite, the resultant flux in the head is zero. As the rotor is turned further to 180 degrees the voltage in *S* reverses and begins to aid the voltage in *R-B* and oppose the voltage in *R-A*. This increases current *Y* and decreases current *X* to zero. At 270 degrees, the currents are again equal due to zero voltage in *S*. At 360 degrees the initial condition is reached which completes one sinusoidal cycle of flux in the recording head for one revolution of the selsyn rotor. The capacitors and choke produce the desired filtering. The selsyn rotor and the pickup drum are coupled together through worm gearing of the proper ratio. The whole unit is driven by an electric motor.

Figure 2. Block diagram of complete system

Timer Unit

The purpose of the timer unit is to produce accurately timed voltages to control the remainder of the system. The basic timing element is a precision tuning

Figure 4. Circuit for magnetizing pulse generator drum

fork which operates at 1,000 cycles per second. This fork controls the frequency of an oscillator whose output drives three electronic binary decade counters through a square wave and differentiating circuit. Each decade unit divides the frequency by 10. Therefore, the output of the third decade unit is one cycle per second. Voltages which occur at the 0.8 second, 0.9 second, and 1.0 second points in the third decade unit are used to control other units of the system.

The decade circuit used may be described with the aid of Figure 5. Each of the binary sections is as shown in Figure 7. The cross connections between the anodes and grids of the triodes produces an effect similar to a lever pivoted at its middle and below its center of gravity with the ends represented by the anodes. In other words, when the potential of the anode of *V1* is high, the potential of the anode of *V2* must be low and vice versa with no stable point in between. As negative pulses are applied at the input, they trigger the section so that the anode voltage of *V1* alternately goes up and down while the anode voltage of *V2* goes down and up. One pulse causes the section to flip one way and the next pulse flips it back. Each time the anode voltage of *V2* decreases, it delivers a negative pulse at the output which triggers the next section. Since two input pulses causes one complete cycle of the circuit operation and one output pulse is produced, the section divides the input frequency by two.

Four of these sections connected as shown in the outline diagram, Figure 5, constitute a decade counter. The four sections are connected in series by capacitors *A*, *B*, and *C*. Each section is designated by the corresponding number in the binary sequence: 1, 2, 4, and 8. The first pulse applied to section 1 turns its neon lamp on. The second pulse turns section 1 off which applies a pulse through capacitor *A* to section 2 which turns 2 on. This pulse is obtained from the sudden decrease in plate voltage of *V1* (see Figure 7) as transmitted through capacitor *C1*. A third pulse turns 1 on again indicating a total count of two plus one or three. A fourth pulse turns 1 off which turns 2 off which turns 4 on. The fifth pulse turns 1 on. The sixth turns 1 off and 2 on. The seventh turns 1 on and the eighth turns 1, 2, and 4 off and 8 on. The ninth pulse turns 1 on. The tenth pulse turns 1 off which passes a pulse through capacitor *D* to 8, which turns 8 off. In going off, 8 passes a pulse back to 2 through capacitor *E* which keeps 2 from coming on so no sections are on. When 8 went off it passed a pulse to the input of the next decade which turned on its section 1 which is an indication of a count of 10.

Wave Shaper, Gate and Pulse Counter

As in the timer unit, a square wave and differentiator circuit is used to shape the input signal from the pickup. The output of the differentiator goes through an electronic gate, Figure 6, before the signal goes to the pulse counter. This electronic gate is essentially a double triode tube and one resistor connected similar to a cathode follower. One grid is connected to the incoming signal and the other grid is connected to the timing counter which opens and closes the gate. The voltage at the cathode of the gate essentially follows the voltage of the highest grid. Therefore, to close the gate, it is only necessary to raise the voltage of the control grid higher than the highest voltage on the signal grid. The control grid is connected to the plate of one of the frequency dividing elements in the timing counter which is at its high voltage between the 0.8 and 1.0 second time. During the remainder of the 1.0 second cycle, this voltage is lower and is below the lowest value of signal grid voltage. Therefore, the cathode voltage follows the signal grid voltage and the gate is open.

The pulse counter consists of six binary decade units each of which divides the frequency by 10. At the end of a counting period, a count is registered on each decade unit by four neon lights in binary form and is the value of the digit

Figure 5. Outline diagram of a decade counter

Figure 6. Electronic gate

in the total count corresponding to its position relative to the other counters. In other words, if the first decade unit has registered on it a count of four, the second a count of two, the third a count of one, the fourth a count of three, and the fifth a count of one, the speed indication would be 1312.4 rpm.

Counter Position Senser

It is possible to read the speed indication by means of the neon lamps, but it was considered too difficult to be used for this application. To improve the readability and to provide remote indication, a circuit is used which senses the count of the decade units and controls a relay system. This relay system transforms the binary of each decade into a digit which forms part of the final numerical speed indication. An extra triode was used for each binary section to isolate the relays from the counter units. The grid of the triode is connected to a grid of the binary section, and the relay coil is connected in the plate circuit of the triode as shown in Figure 7. *KA* is the reset relay whose contacts are open between the time 0.8 and 0.9 second of each cycle as controlled by the timing counter through *V4*. *KB* is the transformation relay. When the reset relay *KA* opens, the transformation relay *KB* is allowed to change positions if necessary to correspond to the count on the binary section. To further explain the operation, assume that the neon lamp (*N*) was out, and on a succeeding operation of the reset relay it happened to be lit. Before relay *KA* opened, *KB* would be in the position shown. When *KA* opened, the grid of *V3* would be high and current would flow through coil *KB*, and operate its contacts. When *KA* closed again, there would be a circuit which would lock *KB* in this position, until at the end of some succeeding counting period when the neon lamp was out.

Figure 7. Binary section and associated relay circuits

Figure 8. Relay and indicator lamp circuit for one digit

Power Tube, Reset Relay, and Counter Resetter

As shown in Figure 2, the power tube receives its signal from the timing counter. This signal voltage is high during the period 0.8 to 0.9 seconds and controls current through the power tube which has the reset relay coil in its plate circuit, Figure 7. The reset relay operation allows the relays in the relay unit to change during the 0.1-second period during which it is energized. As the reset relay *KA* closes, one set of its contacts closes a circuit from the plate supply voltage through the counter resetter relay, coil *KC*, and a capacitor, *C2*, in series to ground. The capacitor charging current is sufficient to close the counter resetter relay for approximately 0.05 second. The normally closed contacts of *KC* upon opening interrupt the current in the cathode lead of all triodes corresponding to *V2* in all binary sections. This interruption forces all the counters to their zero count position in preparation for the next counting period.

Automatic Range Changer

As mentioned previously, the pulse generator has two tracks of magnetic poles on its rotor with a pickup above each track. At 4,000 rpm the system automatically switches from the high-frequency pickup to the low-frequency pickup to decrease the signal frequency. To account for this frequency decrease of 10 to 1, the signal is applied to the units decade instead of the tenths decade. In this way, the decimal point remains fixed. The only difference is that the tenths decade always registers zero at speeds above 4,000 rpm, and the indication is accurate to 1 rpm. The transfer is automatically accomplished by detecting when the speed reaches 4,000 rpm. A voltage is available in the thousands decade which gives a negative pulse each time this decade unit reaches a count of four. This negative pulse is used to trigger a 2-section binary counter. Each of the two binary sections controls a relay in the same manner as the other counters. The 2-section counter was used because at 4,000 rpm one pulse occurs, and at 14,000 rpm, another pulse occurs, which turns the first section "off" and the second section then goes "on." Therefore, if either of the binary sections are "on," the relay connected to that section serves as a control for the range transfer relay. Since the relays of the 2-section counter are controlled the same as the other counter relays, they cannot change except during a regular reset period. In this way, no error occurs due to the transferring action.

Relay Unit and Indicator

Figure 8 shows the circuit for transforming the binary count on the decade units to a direct-numerical type of presentation. This circuit shows the operation for a single digit. The four sets of relay contacts on the right are connected to indicator lamps such that the proper lamp is lit to indicate the value of the digit as registered on the decade unit. By using a d-c power supply and the rectifiers, this simple circuit using few relay contacts was found desirable.

The indicator could have been made by providing a column of ten labeled lamps per digit. With this type of indication, it would be necessary to scan the whole panel and pick out the light which was lit in each column to make the complete reading. This type of indication was considered too awkward and difficult to read. To simplify the indicator reading, number stencils were illuminated with the lamps and the images of each column of ten stencils were focused at a single spot on an opal glass screen. This was accomplished by mounting the optical tubes, each containing a lamp, a stencil, and a lens; on a cylindrical surface whose axis is horizontal. Figure 9 shows the inside of the indicator. The tubes are threaded into an aluminum plate which allows for focus and alignment adjustments. The numbers at the bottom and top of the cylindrical frame appear somewhat elongated when viewed on the screen but it was not considered objectionable. This could have been corrected by changing the shape of the numbers. An acceptable material found for the screen was flashed opal glass. The indicator is readily readable in ordinary room light, but the contrast is increased if no direct light falls on the indicator screen. Several indicators may be used simultaneously.

Figure 9. Top view of indicator removed from case

Calibration

Since this tachometer is more accurate than any calibration device normally available, means were devised so that it could be used to check itself. One means was built into the system which checks everything except the pulse generator and the frequency of the tuning fork oscillator. By pressing a button, a relay operates which connects the oscillator output to the input of the tenths decade in the pulse counter. The first three digits then indicate 800. Since the ten thousands decade is not designed to count beyond three, the remaining three digits are checked by connecting them to a point in the tenths decade where the 1,000-cycle oscillator frequency is divided by five. Therefore, since each group of three counters counts for 0.8 second, the reading should be 160800 exactly. This checking relay also disconnects the output of the third decade from the input of the fourth decade. Several means are available for checking the tuning fork frequency.

One way is to connect both the oscillator output and a frequency standard to an oscilloscope and observe the rate of change of the pattern. A second means is to connect a frequency standard to the generator cable and observe the tachometer indication. The indication should be 0.8 of the frequency of the supply. A more elaborate system of checking, which checks the entire tachometer except the 1,000-cycle frequency and the sixth decade counter is to connect the generator low-frequency signal to the timing counter and the high-frequency signal to the regular counting unit at the same time. To decrease the timing cycle repetition rate, an extra decade unit is inserted in the timing counter. In this way, the generator controls the timing period as well as the pulses counted, and the tachometer reading should be the same regardless of speed. The timer unit will require 10,000 counts per cycle and will allow counts to accumulate in the main counter during 8,000 counts. Since the high frequency is accumulated in the main counter, the indication will be 80,000. The system can be checked over a wide range of frequency by varying the generator speed.

Conclusion

The performance of this tachometer has been highly satisfactory in actual use. A unit is being used with other instruments to test the efficiency of steam and gas turbines. Output power is obtained from speed and torque measurements. The accuracy of this output power measurement has been appreciably improved by the use of this tachometer. Although torque meters are not as accurate as this tachometer, they are being improved.

Four outstanding advantages of this tachometer, namely high accuracy, readability, minimizing of calibration error, and minimizing of human error in reading make it desirable for many applications in development testing, production testing and in use as a calibrating standard for other tachometers.

Discussion

C. M. Gardiner (General Electric Company, Schenectady, N.Y.): It has long seemed strange to this writer that accurate measurements of such fundamental things as speed, torque, and electric power should be as difficult as they are. During a number of years of active work in conducting acceptance tests on large steam turbine-generator sets, it was found that, in almost every case, one of the most significant errors affecting the net result was that incurred in measuring electrical output. Subsequent experience in the operation of turbine research testing equipment emphasized the lack of accurate and convenient devices for the measurement of speed and torque. A system had been developed for measuring speed by recording the time required for a specified number of revolutions, with which, by using an accurate time recorder, and counting a sufficiently large number of revolutions, a very good value of average speed could be obtained. The work of computing the results from the recorded times, however, was inconvenient, and since results were not available until a run had been completed, they could not be used to adjust speed, or to indicate variations therein during a test. No device of any type was available which could consistently measure torque with an accuracy of 0.1 per cent.

In view of these things, the development of an indicating instrument which can measure speed to better than 0.1 per cent, and do it without reservations of any kind over a range of 40-to-one, represents a definite forward step in the measuring art. While the device itself appears complicated, its designers seem to have done a good job of keeping the complications within the machine, and of safeguarding it so that failures which might occur can be readily detected and will not result in erroneous readings.

This instrument should be valuable to large research organizations which have frequent demands for a means to measure speed accurately. It also should have an application in places where a number of tests are running concurrently, each of which requires a measurement of speed. In many such cases an accurate indication as often as once per minute would be adequate, and by attaching a pulse generator to each unit whose speed is to be measured, and wiring these all to one counting element, this element could, with some modifications, be made to print the speed of each unit once per minute on a paper tape and, if desired, also to indicate the speed at one or more remote points on the same type of indicator as described in the paper. At a rate of once per minute, it could indicate and record the speeds of 60 different machines.

The basic elements of this tachometer also should find application in the precise control of speed or frequency. Information could be obtained to indicate deviation of speed from any desired standard, and a measure of the deviation could be supplied to corrective mechanisms; or with equal facility, information could be obtained to indicate the total accumulated angular error, and corrections could be applied to hold this to a small value.

Undoubtedly control systems and research investigations will continue to have need for increasingly accurate speed measurements and the tachometer described in this paper should fill many needs which previously could not be met with commercially available equipment.

Frank D. Olney (General Electric Company, Fort Wayne, Ind.) Experience in testing fractional-horsepower motors with an electronic counter-type tachometer similar to the one described in this paper suggests the following points:

1. In comparison with other types of tachometers, the counter-type is very near to a primary standard in that it counts revolutions for a certain interval of time instead of converting rotational speed into voltage or spring force or some other secondary quantity—that is, the counter-type tachometer is a digital computer rather than an analogue computer. By the method described in this paper, a tenfold improvement in accuracy has been made possible, so that the speed reading becomes the most accurate test quantity instead of the least accurate as has previously been the case.

2. The authors state that a neon lamp indicator composed of ten labeled lamps per digit is too awkward and difficult to read. In order to simplify the indicator reading, they provided a fairly complicated projection system using illuminated stencils focused at a single spot on a glass screen. While this is a novel solution of the problem, our experience shows that it is not difficult to read a 4-digit number in which each digit is in a separate column, and that the neon lamp indicator gives satisfactory results with a considerable saving in cost over the projection system.

3. An important feature of this tachometer where industrial usage is concerned is that any electron tube may be replaced

without affecting the speed reading, since the counting circuit is of the "on-off" type.

4. Since each speed reading is spaced one second apart, this tachometer can be used to make accurate speed-time deceleration curves simply by removing power from the rotating machine and calling off each speed reading into a recording machine. This application of the tachometer was suggested by one of our engineers who is interested in obtaining values of windage, bearing friction, and core loss of small motors without the necessity for taking oscillograms.

5. This tachometer can be used as a time-interval meter to measure the time-interval between two events by counting the oscillations from the tuning fork during the interval. At an oscillation rate of 1,000 cycles per second, a unit on the indicator scale will represent an elapsed time of one millisecond.

6. By reading the speed of a small synchronous motor, this tachometer can be used to measure line frequency more accurately than can be done by the usual frequency meter. On one large power system, the frequency swing is from 59.9 to 60.1 cycles per second during the day, which causes a spread of six rpm in the full-load speed of a 4-pole motor operated from the power line. Correction for this frequency deviation should be made in development testing where extreme accuracy is required.

7. With further development of binary counting circuits which were first used extensively for radar applications, it seems reasonable to expect that the cost and physical size of the electronic counter tachometer will be drastically reduced in the future.

C. L. Beattie: Mr. Olney has made several interesting comments and suggestions for special applications of the tachometer.

The projection type of number system was used for convenience and to facilitate the reading of the indicated speed values every second. This is particularly desirable for long tests to prevent eye strain and fatigue.

In many applications a conventional type of indicating decimal counting unit may be used.

A Direct Reading High-Voltage Capacitance Bridge

A. H. FOLEY
ASSOCIATE AIEE

Synopsis: In contrast with the conventional Schering bridge, the network described in this paper is direct reading for both dissipation factor and capacitance, has a fixed guard adjustment, and hence simplified operation. A unique method of phase-angle compensation employs adjustment of the effective phase angle of the standard capacitor. This compensation may be either positive or negative as required. Design is simplified since compensation for stray wiring capacitances is easily accomplished. Simplified operation and elimination of all calculations permit substantial reductions in unit testing time and operation by nontechnical personnel without sacrifice of accuracy.

A GENERAL survey of high-voltage capacitance bridges in use throughout the electrical industry has shown the need for a bridge specifically designed for production measurement of capacitors and similar devices. For this purpose a bridge has been developed which is direct reading in both capacitance and dissipation factor and which does not require a guard balance for most measurements. The use of this bridge should result in the saving of several thousand dollars per year where large quantities of capacitors must be checked daily as on a production line or in the development laboratory.

It was with a view toward increasing testing efficiency that the direct reading bridge described in this paper was developed. Though the Schering bridge network is in quite general use for capacitance and dissipation factor measurements at high voltage, especially at low frequencies, and provides accurate test data, the conventional arrangement of the network does not generally provide direct readings for both capacitance and dissipation factor. At least one of these quantities usually must be computed from the readings obtained. These factors led to the development of the direct reading bridge network, which, though similar fundamentally to the Schering network, differs from the Schering bridge in a number of technological details.

The development also has been directed toward a unit package containing, as far as possible, all components of the bridge. Examples of direct reading capacitance bridge designs for large capacitances are shown in Figures 1 and 2. The unit shown in Figure 1 was designed for the measurement of power factor correction capacitors at rated voltage and frequency on the factory production line. Here, a capacitance accuracy of ±0.1 per cent and a dissipation factor accuracy of better than ±0.0001 is maintained for rapid production measurements by nontechnical personnel.

The principle objective of this paper is to introduce the direct reading capacitance bridge network. The discussions which follow, though principally theoretical, often present the practical side of the bridge design.

Comparison of the Direct Reading and Schering Bridge Networks

The basic circuit of the direct reading bridge is shown in Figure 3(A). For purposes of comparison the Schering bridge network is shown in Figure 3(B). In these two figures C_s represents the standard capacitor while C_x and ρ represent, respectively, the capacitance and effective series resistance of the capacitor under test. The bridge balance detector is indicated as G.

The remaining elements, all operating at low potential, complete the two networks and are either fixed or adjustable resistances and capacitances employed in balancing the bridges. In the discussion to follow it will be assumed that a power source of fixed frequency is used, a condition most generally met in practice.

The Schering Bridge Network

A brief review of the Schering bridge network[1] will clear the way for a quicker understanding and appreciation of the advantages of the direct reading network. Referring to Figure 3(B), when the network is balanced the capacitance of the test capacitor is

$$C_x = \frac{C_1 R_3}{R_2} \tag{1}$$

while the dissipation factor (tangent of the defect angle) is

$$D_x = \omega C_1 R_3 \tag{2}$$

where

$\omega = 2\pi f$

If it is chosen to make the Schering bridge read capacitance directly, capacitance balance can be made by adjusting either C_x or R_3. Since C_x is usually a guarded high-voltage air capacitor it is impractical, all points considered, to construct it to have a continuously variable capacitance. Furthermore, manipulation of this high-voltage element is generally undesirable from a safety point of view. This quickly rules out the use of C_x as an adjustable element for balancing capacitance when measurements are to be made at high voltages. On the other hand R_3, operating entirely at low potential, is easily made variable over a wide range. Since R_3 is a direct function of C_x, the controls on R_3 may be calibrated to read capacitance directly. If this is done, however, two variables, C_1 and R_3, are involved in determining the dissipation

Paper 50-110, recommended by the AIEE Instruments and Measurements Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE North Eastern District Meeting, Providence, R. I., April 26–28, 1950. Manuscript submitted November 18, 1949; made available for printing March 7, 1950.

A. H. Foley is with the General Electric Company, Pittsfield, Mass.

Figure 1. A 13.8-kv direct reading capacitance bridge designed for the measurement of power factor correction capacitors on the production line by nontechnical personnel

factor of the test capacitor. A direct calibration of C_3 for dissipation factor is not possible. With such an arrangement dissipation factors must be computed employing equation 2.

A direct calibration of C_3 for D_x can be made only when R_4 is fixed. It then becomes necessary to adjust R_4 in order to make a capacitance balance, but since R_4 is an inverse function of C_x, a direct capacitance calibration cannot conveniently be made without employing special resistance controls. One form of such control for R_3 is the conductance decade. While conductance decades can be calibrated to read capacitance directly, it is very difficult to construct a system of decades which will cover a wide range of resistance such as 10,000-to-1 or greater, and at the same time permit readings of four or five significant figures to be taken at any point in the range. An additional difficulty is the problem of maintaining good phase-angle characteristics for R_4 over this extremely wide resistance range. A third difficulty arises when large capacitances are to be measured, particularly at high voltage; the charging currents become quite large, hence switch contacts and heating of the resistance elements must be given special attention.

It is to be concluded from the foregoing discussion that, in general, the Schering bridge conveniently can be made to read directly for one quantity only, either capacitance or dissipation factor. One of these must be computed from the bridge readings. While this discussion makes no pretense at covering all possible modifications of the Schering bridge network, it is believed that a more general discussion will lead essentially to the same conclusion.

The Direct Reading Network

Having thus reviewed the basic Schering bridge circuit, the direct reading bridge network now can be considered in some detail. Referring to Figure 3(A) it will be noted that a resistance potentiometer, comprised of resistances R_1 and R_2, replaces resistance R_2 of Figure 3(B). Capacitances C_1 and C_2 effect phase angle compensations in a manner to be discussed later. It can be shown that, very closely, when the network is balanced

$$Cx = \frac{C_3 R_3}{R_2} \tag{3}$$

and, for proper phase-angle compensation

$$Dx = \omega C_1 (R_1 + R_2) \tag{4}$$

It is a simple matter to arrange the resistance potentiometer so that R_2 is proportional to the potentiometer dial settings. Hence, by suitable choice of R_3, the potentiometer controls can be calibrated to read C_x directly.

Since resistances R_1 and R_2 comprise a

Figure 2 Examples of portable 2-kv direct reading capacitance bridges for (left) quality control measurements, and (right) developmental measurements on small a-c capacitors. Both units are complete with power supplies and safety test cubicles

Figure 3 (left). Basic bridge networks. (A). Direct reading. (B). Schering

Figure 4 (right). (A). The direct reading bridge network with standard capacitor guard system. (B). The standard capacitor phase angle control network

potentiometer, the sum of the two is a constant. If $R_1+R_2=R_p$, equation 4 can be rewritten

$$Dx=\omega C_3Rp \tag{5}$$

Only one variable, C_3 is involved in determining the dissipation factor hence a direct calibration for D_x can be made on the dials controlling C_3.

Direct readings for both C_x and D_x can thus be obtained without making R_3 continuously variable. In covering a wide capacitance range, say 100-to-1 or more, it is desirable to vary R_3 but this most conveniently can be done in decade steps thus preserving the direct reading feature, as regards significant figures, of the R_3 calibration.

The use of decade step values for R_3 also makes it unnecessary to vary R_2 through more than a 10-to-1 range no matter how wide the total capacitance range of the bridge might be. This provides still another advantage; capacitance readings of any desired number of significant figures at any point in the bridge capacitance range can be obtained by employing a decade potentiometer system for (R_1+R_2) and simply providing a single decade for each desired significant figure.

Theoretical and Practical Considerations

A complete solution of the balance equations for the direct reading network, Figure 3(A), is unwieldy and would serve no useful purpose in the present discussion. It is sufficient to say that after certain high order terms are omitted the capacitance, C_x, of the test capacitor is given quite accurately (in typical cases the error will be less than 0.001 per cent) by equation 3. Similarly the dissipation factor, D_x, is very closely (error generally less than 0.00001)

$$Dx=\omega Cxp=\omega C_x(R_1+R_2)+\omega C_3R_1+\omega C_1R_2-\omega C_3R_3 \tag{6}$$

Equation 6 takes into account all of the parameters shown in the circuit of Figure 3(A). The terms on the right of the equation are, respectively, the tangents of the phase angles created by C_3 in combination with (R_1+R_2), R_1 in series with C_x, C_1 across R_3 and C_3 across R_3. Thus the effect of R_1 in series with C_x is to destroy the purity of the standard capacitor. Also, C_1 across R_3 further increases the phase-angle error on the left-hand side of the network, Figure 3(A). However, if C_1 is made equal to C_x, equation 6 becomes

$$D_x=\omega C_3(R_1+R_2)+\omega C_x(R_1+R_2)-\omega C_3R_3 \tag{7}$$

Since C_x and (R_1+R_2) are constant the second term on the right of equation 7 becomes constant and can be completely neutralized by making $C_3R_3=C_x(R_1+R_2)$. In fact, the sole function of C_3 in the network of Figure 3(A) is that of phase-angle error compensation. Another, and more satisfactory, means of compensation will be described later.

To be thoroughly practical, C_3 should be considered as composed of two parts: the minimum or residual capacitance below which C_3 cannot be set; and the variable component of C_3. If these are represented by C_r and C_d, respectively, equation 7 becomes

$$D_x=\omega C_d(R_1+R_2)+\omega C_r(R_1+R_2)+\omega C_x(R_1+R_2)-\omega C_3R_3 \tag{8}$$

Complete neutralization of the two error terms of equation 8 now can be affected by making $C_3R_3=C_r(R_1+R_2)+C_x(R_1+R_2)$. Thus, for zero phase-angle error

$$C_3=\frac{(C_x+C_r)(R_1+R_2)}{R_3} \tag{9}$$

The last three terms of equation 8 being thus eliminated, the equation reduces to the simple expression

$$D_x=\omega C_d(R_1+R_2) \tag{10}$$

The practical significance of including C_r in equation 8 is that only the straight line portion of any variable air capacitor employed for C_3 needs be calibrated. A linear scale is thus provided for the dial calibration on C_3. Furthermore, the scale can start at $D_x=0$ rather than at some point above zero as would be the case were C_r not neutralized. It is at once apparent that C_r may be composed not only of the residual portion of the capacitor used for C_3 but also the residual wiring capacitance associated with C_3.

Compensation by Control of Standard Capacitor Phase Angle

The use of C_3 for phase-angle compensation is unsatisfactory particularly in a wide range capacitance bridge. Though R_3 may be changed in decade steps, a wide range bridge may employ a large number of such steps and each would have to be shunted with a suitable value of C_3. For bridges designed to measure high capacitances R_3 may be quite low and the associated value of C_3 very large; in some cases tens of microfarads.

A unique and improved method of compensation, one which eliminates the use of C_3 altogether, makes use of adjustments of the effective phase angle of the standard capacitor, C_s. The method is such that the effective phase angle of C_s may be adjusted with precision in either a positive or negative direction, as required, and should find application in circuits other than those considered here. The circuit for accomplishing this is shown in Figure 4(A). C_s is shown as a guarded capacitor. This, in itself, differs in no way from common practice with high-voltage bridges. The difference lies in the manner in which it is operated.

In conventional bridge practice, R_g is adjusted until points 4 and 5, Figure 4(A) are substantially at the same potential. Then no current can flow through C_{gs}, the capacitance between the low potential electrode of C_s and the guard ring surrounding that electrode. In this way the purity of C_s, with reference to effective phase angle, is preserved.

In the method of compensation under

discussion here, points 4 and 5 are not operated at the same potential. It will be shown, however, that the effective phase angle of C_s can be adjusted precisely in either a positive or a negative direction from the angle obtained when points 4 and 5 are at equal potentials and that the phase angle so obtained can be employed to compensate for the sum of all other constant phase angle errors in the network.

An approximate analysis is presented here in order to give a clearer physical picture of the compensation circuit performance. If the left-hand side of the network is examined, three capacitances will be observed to be involved in the standard capacitor system, namely, C_s, the direct capacitance between high-and low-voltage electrodes, C_g, that between the high-voltage electrode and the guard ring, and C_{gs}, that between the guard ring and the low-voltage electrode. Tracing the left-hand side of the network between points 1 and 3 it is seen that the network of Figure 4(B) is obtained if C_1 and C_3 are omitted. Since, in practice, the ratio of the reactance of C_s to resistance (R_1+R_2) is quite high (1,000-to-1, or more in typical cases) the component of voltage across (R_1+R_2), due to current through C_s, is closely

$$E_{3-4}=j\omega C_s(R_1+R_2)E_{1-3} \tag{11}$$

Likewise, the voltage across R_g, due to current through C_g, is

$$E_{3-5}=j\omega C_gR_gE_{1-3} \tag{12}$$

Equations 11 and 12 hold closely because, in practice, the difference between potentials E_{3-5} and E_{3-4} is impressed across C_{gs} and causes a current to flow through C_{gs} which is quite small compared to currents flowing through C_s and C_g.

Consider, separately for the moment, the current through C_{gs}. This current flows principally around through (R_1+R_2) and R_g thus creating a component of voltage across (R_1+R_2) which is closely

$$E_{3-4}'=j\omega C_{gs}(E_{3-5}-E_{3-4})(R_1+R_2) \tag{13}$$

Substituting equations 11 and 12 in equation 13

$$E_{3-4}'=\omega^2C_{gs}E_{1-3}[R_1+R_2][C_s(R_1+R_2)-C_gR_g] \tag{14}$$

Equation 14 shows that we can get a component of voltage across (R_1+R_2), due to current flow through C_{gs}, which is essentially in quadrature with the principal component across (R_1+R_2). If C_gR_g is greater than $C_s(R_1+R_2)$, E_{3-4}' is negative.

Clearly then, the effect of E_{3-4}' on the total voltage drop across (R_1+R_2) is to

Figure 5. Methods of guarding. (A). For high-capacitance bridges. (B). For low-capacitance bridges

shift its phase by a small angle, ϕ_s. This angle, which can be defined as the effective phase angle of C_s, is closely

$$\phi_s=\tan^{-1}\frac{E_{3-4}'}{E_{3-4}} \tag{15}$$

Upon substituting equations 11 and 14 in equation 15

$$\phi_s=\tan^{-1}\omega C_{gs}[R_1+R_2-\frac{C_g}{C_s}R_g] \tag{16}$$

From this equation the value of R_g, for any desired small value of tan ϕ_s, is

$$R_g=\frac{C_s[\omega C_{gs}(R_1+R_2)-\tan\phi_s]}{\omega C_gC_{gs}} \tag{17}$$

Referring again to equation 8, it is seen that the magnitude of the angular error for which neutralization is required is $\omega C_r(R_1+R_2)+\omega C_s(R_1+R_2)$. These terms express the tangents of the error angles discussed previously, each representing a constant phase angle at fixed frequency. Clearly then, if these terms are to be neutralized by adjusting the effective phase angle of C_s, tan ϕ_s must be made equal in magnitude and opposite in sign to their sum. Thus, for correct compensation

$$\tan\phi_s=-\omega C_r(R_1+R_2)-\omega C_s(R_1+R_2) \tag{18}$$

Substituting equation 18 in equation 17

$$R_g=\frac{C_s(R_1+R_2)(C_s+C_{gs}+C_r)}{C_gC_{gs}} \tag{19}$$

Note that R_g is independent of frequency. When the conditions of equation 19 are satisfied, equation 8 again reduces to the simple expression

$$D_x=\omega C_s(R_1+R_2) \tag{10}$$

The Service Guard Circuit

At this point those familiar with high-voltage bridge practice will raise the question concerning a guard circuit for use when measuring guarded test specimens. R_g having been fixed for compensation purposes, the circuit, as shown in Figure 4(A), is without a service guard. The practical answer to this question is determined by the range of capacitances to be measured.

For large capacitances, say of the order of 0.1 microfarad and greater, guarded capacitors are seldom encountered. They are almost invariably two terminal units. For such units there is no need for a service guard. There is a need, however, for a shield around the low-voltage lead which connects the test capacitor to point 6 as shown in Figure 5(A). The shield is simply connected to point 3, commonly grounded. The added capacitance which this arrangement places across R_g is usually negligible since, for large capacitances, R_g is small (typically less than one ohm).

The circuit arrangement shown in Figure 5(A), which is for the measurement of large capacitances, has the important advantage of not requiring a guard balance each time a capacitor is measured. This very materially simplifies the bridge operation and permits measurements to be made on large quantities of capacitors with substantial reductions in time. Examples of designs of direct reading bridges taking advantage of this feature are shown in Figures 1 and 2.

For the measurement of small capacitances, a service guard is definitely needed. For this purpose an auxiliary high-voltage capacitor, C_4, and an adjustable resistance, R_4, are required as shown in Figure 5(B). The question of cost of the auxiliary high-voltage capacitor, C_4, invariably arises. Since a guarded capacitor is not needed for this application, a relatively inexpensive vacuum capacitor or other type of 2-terminal capacitor usually will be satisfactory.

Standard Capacitor Design

The practical application of phase-angle error compensation by means of standard capacitor phase-angle control requires, among other factors, that the voltage across R_g, Figure 4, be stable. Hence a few words concerning the design of the standard air capacitor are in order.

It is common practice to design guarded air capacitors with only three terminals, one for the high-voltage electrode, one for the low-voltage electrode and one for the guard rings or cylinders. In some designs of this type there can be an appreciable leakage both through and over the surfaces of the supporting insulation between the high-voltage electrode and the

Figure 6. A 13.8-kv 4-terminal standard air capacitor suitable for use with the direct reading capacitance bridge. (Left) assembled unit (Right) component parts

guard rings. Such leakage may not be stable. In any case it causes an additional current to flow through R_x and thereby alters the potential drop across this resistor.

This effect can be satisfactorily overcome by employing a 4-terminal standard, that is, one with a leakage interceptor electrode between the high-voltage electrode and guard rings. This fourth terminal generally can be connected to the low-potential supply line (point 3 in Figure 4(A)). An example of 4-terminal guarded air capacitor design is shown in Figure 6. The capacitor is of the concentric-cylinder type with the high-voltage electrode supported on insulators from a steel base plate. The lower guard cylinder, see Figure 6(B), is insulated from the base plate on insulation independent from that supporting the high-voltage cylinder. The base plate thus becomes the interceptor of any leakage through or over the surfaces of the high-voltage insulation.

Adjustment of C_1 and R_x

It has already been shown that, in order to hold certain of the network phase angles constant, C_1 must be equal to C_x, the standard capacitor. A part of C_1 easily may be in the form of distributed wiring capacitance across R_3. A portion also may exist between point 2 of the detector and point 3 (usually ground). An experimental method of adjusting C_1 makes it unnecessary to know the magnitude of these stray capacitances.

The method is based on the requirement that the slope of the curve of dissipation factor calibration versus C_x, with C_x as the abscissa, be zero. In other words, if D_x is held constant at any point and C_x varied, there should be no change in the setting of C_3. Equation 6 shows that this condition can be realized only when $C_1 = C_x$.

For bridges designed to measure capacitances in the range between, say, 100 and 1,000 micromicrofarads, two guarded air capacitors having a ratio of some three to one or more (but not more than ten to one) between their respective capacitances will be useful in adjusting C_1. The lower unit preferably should have a capacitance between 100 and 300 micromicrofarads so that, when the unit is connected to the bridge as C_x and the bridge balanced, the ratio of (R_1+R_3) to R_2 approaches ten. When the larger of the two guarded capacitors is in place and the bridge balanced, this ratio should approach unity. Then, if both capacitors have equal or zero dissipation factors, the setting of C_3 will remain unchanged for the two measurements only if C_1 is properly adjusted. It is simply a matter of experimentally adjusting C_1 until the slope is zero.

A particularly useful type of guarded air capacitor for adjusting the direct reading bridge is shown in Figure 7. This is a guarded decade air capacitor having ten steps of 100 micromicrofarads each. A selector switch is provided for setting the capacitance. Only the low-voltage electrodes are switched. Electrodes not in use for direct capacitance are simply switched into the guard circuit as the selector switch is set.

With the aid of this type of guarded air capacitor, a most thorough check can be made of the setting of C_1 and, at the same time, any variations in the phase angle of R_3 can be evaluated. Such variations cause the curve of dissipation factor calibration versus C_x to depart from a straight line.

An added advantage of employing

Figure 7. A 2-kv 1,000-micromicrofarad 4-terminal decade standard air capacitor. Very thorough phase angle checks can be made on capacitance bridges with the aid of this unit. (Left) assembled unit (Right) component parts

guarded air capacitors having dissipation factors of essentially zero in the manner described before is that, once C_1 has been set, R_g can also be set for proper phase-angle compensation. This is done simply by setting C_3 to the point arbitrarily calibrated as $D_x=0$ and then adjusting R_g and R_3 until the bridge is balanced. This procedure makes it unnecessary to determine the magnitudes of either C_p, C_{gs}, or R_g.

For direct reading bridges designed to measure only large capacitances a somewhat different procedure must be followed in adjusting C_1. The method consists, essentially, in choosing a number of capacitors such as, for example, the impregnated-paper type, all having the same nominal capacitance. The capacitance and dissipation factor of each is measured on the bridge just as it stands before adjustment of C_1. The capacitors are then connected in parallel in groups of two, three, and so forth, and remeasured on the bridge. The results of the group measurements are then compared with the value of capacitance and dissipation factor as computed from the individual readings.

An example will make the procedure more readily understood. Suppose R_3 is set so that the bridge will measure capacitances between 1 and 10 microfarads. Ideally a group of ten 1-microfarad capacitor would be employed for a very thorough check but this would call for an excessive number of measurements. It would be more practical to choose, say, four 2.5-microfarad capacitors. When all four units are in parallel they can still be measured on the same range of the bridge, as set by R_3. If the individual measurements give results as shown in Table I, then the dissipation factors of parallel combinations of capacitors may be computed from the equation

$$D' = \frac{C_1D_1 + C_2D_2 \ldots + C_nD_n}{C_1 + C_2 \ldots + C_n} \qquad (20)$$

Substituting the figures in Table I in equation 20 yields the results shown in Table II.

The procedure now is to measure the parallel groups as arranged for the computation. If the measured dissipation factors differ from the computed values, C_1 must be adjusted, experimentally, to bring about an agreement. Note that any adjustment of C_1 also will affect the dissipation factor readings as taken on the individual units. After each adjustment of C_1 a complete new set of readings must be taken and computations made. Convergence, however, generally is rapid and two or three "runs" usually is sufficient to adjust C_1 for the required zero slope.

The Bridge Balance Detector

In general, any detector suitable for use with the Schering bridge network is suitable for use with the direct reading bridge. Detector systems composed of a tuned amplifier and an output meter are especially good if designed so that inductive elements are not included in the low-level signal circuits. A particularly satisfactory type of circuit[2] employs a high gain resistance coupled amplifier in conjunction with a resistance-capacitance twin-T network through which selective negative feedback is obtained. Detector systems of this type have the advantages of low susceptibility to pickup from magnetic fields, fast response, high discrimination against harmonics (virtually always present in any power bridge), high signal sensitivity, and ruggedness.

Table I

Summary

The direct reading bridge network, while retaining the advantage of the Schering bridge network by keeping all adjustable elements in the low potential arms, has the additional advantage of providing direct readings for both capacitance and dissipation factor. Furthermore, large amounts of stray wiring and other capacitances are easily compensated for without knowing their magnitudes. A useful feature in checking the bridge performance, one not common to the Schering bridge when R_3 is employed for the capacitance balance (as is most generally done), is that the bridge can be balanced when the test capacitor arm is completely open. If any stray capacitance exists across this arm it then can be read directly from the bridge dials.

These desirable features, together with the complete absence of an adjustable guard where large capacitances are to be measured, make the direct reading bridge exceptionally easy and fast to operate, even by nontechnical personnel, at no sacrifice in accuracy and without the necessity for any computations.

Discussion

E. H. Povey (Doble Engineering Company, Belmont, Mass.): There seems to be a prejudice against the use of any bridge circuit which cannot be resolved simply and with mathematical rigor. In the case of the circuit described in this paper, the peculiar advantages offered by the circuit should go far in overcoming any such prejudice. The author has done an effective job in designing the circuit from the viewpoint of the operator.

The description of the bridge leaves the impression that the phase angle control network shown in Figure 4(B) is necessarily associated with the construction of the standard capacitor. However, C_g and C_{g2} can be separate components. For phase control in one direction only and at a fixed frequency, these capacitors may be replaced by resistors.

In some bridge applications it may not be feasible to keep the residual capacitance C_3 very small, and phase angle errors will be introduced as decade arm R_3 is switched. These errors can be avoided by the use of shields and a guard balance as shown in Figure 5(B). Another method is to compensate for the errors by proper adjustment of the phase angle control network. The adjustment is most simply made by changing the value of R_g, and if the switch for performing this function is mechanically linked to the R_3 switch, the adjustment will be automatic.

A. H. Foley: Mr. Povey has pointed out a certain lack of completeness in the paper on a direct-reading capacitance bridge. It was not the author's intention to give the impression that the phase angle control network, Figure 4(B), is necessarily associated with the construction of the standard capacitor. In fact there usually is a definite advantage in padding C_{g2} by means of additional external capacitance. In practice C_{g2} is perhaps the least stable of all the parameters in the network. Thus by placing some additional capacitance of a stable nature across C_{g2} and readjusting R_g in accordance with the total capacitance between points 4 and 5, a more stable phase-angle control usually is achieved.

C_g and C_{g2} can indeed be separate components. A useful application of the phase angle control network is where a small voltage is required in accurate quadrature relationship with respect to the voltage between points 1 and 3. In this case the entire network can be made up of separate components using, for example, mica capacitors as C_x, C_g, and C_{g2}. Using equation 17, tan ϕ_g must be set equal to $-[\omega C_x(R_1 + R_3) + \tan \phi_{cx}]$ where tan ϕ_{cx} represents the dissipation factor of the capacitor used as C_x. This results in the equation

$$R_g + C_3 \frac{\omega(R_1+R_3)(C_{g2}+C_3)}{\omega C_g C_{g2}} + \tan \phi_{cx}$$

for a pure quadrature voltage across $(R_1 + R_3)$.

While C_g and C_{g2} may be replaced with resistors, the direction of phase-angle control which can be obtained is opposite to that required for compensation of the error terms considered in the paper. Also, the resistor replacing C_g would have to operate at high voltage and might pose a practical problem as regards construction and stability.

Mr. Povey's suggestion to mechanically link the R_3 switch and a switch controlling R_g to obtain correct compensation for phase-angle errors in R_3, where several values of R_3 are used, seems practical and should further help to realize direct readings and eliminate the necessity for applying corrections.

Power Measurement by the Hook-On Method

A. J. CORSON
MEMBER AIEE

A. L. NYLANDER
NONMEMBER AIEE

THE "hook-on method" is here defined as the measurement of an electrical quantity, where the current component of such measurement is obtained by encirclement of the current-carrying conductor by a removable magnetic structure. This magnetic structure provides a circuit for the magnetomotive force, which force is a unique function of the current and is applied to a secondary winding, or directly to an instrument mechanism. Available self-contained instruments are limited to current measurement. Some of these instruments have independent potential circuits, such as the hook-on voltammeter, illustrated in Figure 1. The authors recently became interested in extension of this measurement method to active and reactive power. This paper is a summary of the development of the self-contained hook-on wattmeter, illustrated in Figure 2. It was necessary that this instrument meet exacting requirements as to accuracy, weight, simplicity of operation, and range of full-scale capacities, 3 to 300 kw.

The Measurement Problem

Since power measurements involve circuits, which will preserve phase-angle relationships, it was evident that a direct application of ammeter magnetic circuits would not necessarily be satisfactory.

Investigation of one such design by application of the secondary voltage to either the fixed or moving coils of an electrodynamic wattmeter showed that only 1/3 of the measurement range of 3 to 300 kw could be covered with acceptable accuracy. The computed and measured phase-angle errors were excessive for the entire measurement range. For this and other reasons, as stated later, the direct acting principle was adopted, even though the development expense was increased some ten-fold by this decision.

The Direct-Acting Instrument

The preferred construction then consisted of a ferrodynamic wattmeter, the field of which is energized by the current carrying conductor through the magnetic hook shown in Figure 3.

The basic torque equation[1] for any electrodynamic (air core) 2-coil system is

$$t_y' = i_1' i_2' dM/dY \qquad (1)$$

where

t_y' = torque at angle Y in dyne centimeters
i_1' = field current in centimeter-gram-second units
i_2' = moving coil current in centimeter-gram-second units
Y = deflection in radians
M = coefficient of mutual induction to centimeters

The application of this equation to a ferrodynamic 2-coil system, with spring-controlled moving system, involves the following considerations:

1. The torque t_y' is translated in angular deflection by the control.

2. For linear scales, the space rate of change of mutual inductance dM/dY must be constant.

An important, but nonrelated observation, is the fact that the scale capacity is directly proportional to potential circuit resistance over a wide current range, and

Paper 50-111, recommended by the AIEE Instruments and Measurements Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE North Eastern District Meeting, Providence, R. I., April 26–28, 1950. Manuscript submitted November 23, 1949; made available for printing March 9, 1950.

A. J. CORSON and A. L. NYLANDER are both with the General Electric Company, West Lynn, Mass.

The authors gratefully acknowledge the assistance of several associates in the development of this instrument, particularly, S. C. Haley, who did much of the original work including the compensation for reluctance torque errors.

Figure 3 (left). Schematic diagram of hook-on wattmeter. Connections for single-phase power measurement also are shown

Figure 5 (above). Linearity deviation characteristic of hook-on wattmeter mutual flux

that range changing can be accomplished by potential switching alone.

The Magnetic Circuit

Returning to the magnetic circuit, it is required that this circuit deliver an appropriate value of useful flux, as a linear function of current, and without a substantial shift in phase angle over a range of 15 to 600 amperes, in order to make equation 1 valid. This was accomplished as follows:

1. The concept of a central core of useful magnetic material, plus a leakage sleeve, was adopted. See Figure 4. The cross section of the leakage sleeve is as close to proportionality with the leakage flux, as manufacture will permit. This objective was closely attained, as shown by the relative flux densities.

2. Air gaps are interposed, as illustrated in Figure 4. The reluctance of these gaps is sufficiently high to dominate the magnetic circuit, and incidentally, to provide insulation between current and potential circuits.

Figure 4. Hook-on Nicalol magnetic structure, showing cross-sectional area proportioned to carry useful flux and leakage flux

3. The magnetic hook must be in such mechanical form, that it can be opened and closed. The effect of the resultant discontinuity in the magnetic circuit is minimized by the use of a long dove-tail joint, as illustrated in Figure 4. This is particularly important where, under difficult conditions, the hook may remain slightly open, due to foreign material or mechanical interference. Also, the resultant flux concentration, with or without partial opening, will limit the maximum principal flux density to values considerably less than the values indicated by the saturation curve of the material used.

It is shown in the Appendix that the required mutual flux is

$$\Phi = T_v \frac{981}{NI} \frac{\pi}{4} \tag{6}$$

Numerical values of the necessary mutual flux are computed by substituting reference condition values in equation 6.

There is an appreciable lagging phase displacement of the mutual flux, with respect to the current over the range of 15-600 amperes. The corresponding phase angle of the potential circuit is practically nil and compensation is therefore necessary. Of the several possible methods, the introduction of a similar phase displacement in the moving coil current by a shunt capacitor is used.

Design Constants and Performance Data

The instruments constants and performance data, Table I, in general, substantiate the predicted values. These test results on a hand-made preproduction sample may be modified when data on significant quantities of tool-made instruments are available. The instrument covers a measurement range of 3 to 300 kw in full scale rating. The equivalent scale length, obtained by multiplying geometrical scale length by the number of ranges, is 15 inches. The low-weight of $3^1/_2$ pounds is obtained by use of the direct-acting principle and suitable proportioning of the hook, as shown in Figure 4. A factor of merit $T/W^{1.5}$ of 0.86, together with a free period of 0.5 second and a damping constant of 2.2 dyne centimeters per radian per second, are ample values for quick, accurate indication, even under adverse conditions of use. The instrument is magnetically damped. The potential circuit rating is dictated by the sensitivity requirement on the one hand and permissible temperature rise on the other. The volt-ampere consumption of the potential circuit is negligible for power system measurements.

Calibration

As for any instrument, there is general agreement as to the use of initial or basic accuracy, plus a tolerance for unusual operating conditions, such as extremely high or low ambient temperature, abnormal wave form, and so forth. The performance data on this instrument are so arranged. Care in the basic design, plus compensation already discussed, result in satisfactorily minimizing errors due to particular conditions. The influence of conductor position in the hook is $2^1/_2$ per cent maximum when using a $^1/_2$-inch diameter conductor in extreme positions. This results from changes, with the conductor position, of the magnetic circuit mmf distribution and leakage patterns.

The scale distribution of the instrument is substantially linear, and departures from linearity, see Figure 6, are a measure of imperfections in alignment of the core, with respect to the pole pieces. Main-

Figure 6. Scale distribution based on mean characteristic of all ranges for best tracking

Figure 7. Reluctance torque effect

Potential circuit alone energized at 150 volts on 3-kw range

tenance of this alignment should insure adequate control of distribution in production. The scale tracking on the six scale ranges is influenced by two factors: magnetization curve of the hook already discussed, and the moving coil reluctance torque. This reluctance torque is due to the circumstance that the total flux linking the moving coil, as a result of moving coil magnetomotive force only, is a function of the coil position. It is a second order effect and is usually negligible in a construction of this kind. In the hook-on wattmeter, however, with its necessarily wide range of moving coil magnetomotive forces, the error is appreciable, when operating under the worst condition, Figure 7. Compensation therefore is necessary.

The reluctance torque is essentially zero at center scale and increases as the scale extremities are approached. Its direction is such that the moving coil tends to return to its central position. Compensation consists of a series magnetizing winding centrally located on the core, Figure 3, thus producing a counter torque of approximately the same relationship as the reluctance torque. Both the reluctance torque and the compensating torque will vary as the voltage squared, so compensation is independent of the applied potential. The necessary concentration of the compensating winding, however, prevents an exact duplicate of the reluctance torque curve; hence, approximate compensation is achieved.

Application

The resulting hook-on wattmeter, illustrated in Figure 2, is applicable to active and reactive power measurements in single and polyphase circuits. Connections are similar to those of the conventional single-phase wattmeter, allowing for the circumstance that the hook surrounds the current carrying conductor. In addition, a 3-phase balanced power measurement, made possible by the hook-on method, is accomplished by the reversed current connection, shown[2] in Figure 8. The current lead number 1 goes through the hook in a direction opposite to that of number 2, resulting in vector addition of the currents and voltages, as shown in the vector diagram.

When V_{13} is applied to the potential circuit, and currents 1 and 2 magnetize the hook, as indicated $(-I_1+I_2)$ at unity power factor, the resultant line voltage and $\sqrt{3}$ times line current are in phase. At any power factor, $\cos\theta$, the instrument will read $\sqrt{3}I_{line}V_{line}\cos\theta$ and is thus direct reading for 3-phase balanced power.

Table I. Instrument Constants and Performance Data

General	Instrument Constants

Figure 8. Three-phase power measurement with single-phase hook-on wattmeter

Conclusion

This development has resulted in the extension of the hook-on method of measurement to include single and polyphase power.

It has been accomplished by the development of an accurate, light-weight, portable, single-phase hook-on wattmeter, having wide measurement range. Simple switching and direct reading scales have resulted in one-hand operation and minimum possibility of error in use.

Appendix

The relationship between the torque and mutual flux is developed as follows:

For a constant permeability magnetic circuit, the coefficient of mutual inductance M' is, by definition, equal to the flux linkages in the moving coil circuit per ampere in the hook circuit, or

$$M' = \phi_m \frac{N}{i_1} \qquad (2)$$

where

ϕ_m = mutual flux, maxwells
N = moving coil turns

substituting in equation 1

$$t_y' = i_2' N \frac{d\phi m}{dY}$$

We now substitute practical units by letting

t_y = torque at angle Y in gram millimeters = $ty'/98.1$
i_2 = current in amperes = $i_2' \times 10$

$$t_y = \frac{(i_2 N)}{981} \times \frac{(d\phi m)}{dY} \qquad (3)$$

The first term, equation 3 represents the potential circuit ampere turns in the moving coil. The second term is the current circuit mutual flux, in maxwells per radian.

At center scale, the mutual flux $\phi_m = 0$ and $Y = 0$.

At full scale, $\phi_m = \phi_{m1}$ and $Y = \pi/4$.

Since the active field is uniform

$$\frac{d\phi m}{dY} = \frac{\phi_{m1}}{\pi/4} = \frac{4}{\pi}\phi_{m1} \tag{4}$$

From equation 3 the full scale torque

$$t_y = \frac{i_2 N}{981} \times \frac{4}{\pi}\phi_{m1}$$

The instantaneous values t_y, i_2, and ϕ_{m1} are converted to rms values by first rewriting this in the form

$$t_{y_1} = K_1 i_2 \phi_{m1}$$

where

$$K_1 = \frac{4}{981\pi}$$

at unity power factor

$$i_2 = I_{max} \sin \omega t$$
$$\phi_{m1} = \Phi_{max} \sin \omega t$$

where

I_{max} = maximum current at full scale
Φ_{max} = maximum flux at full scale

If the free period of the instrument greatly exceeds the period of the current and flux, the average torque

$$T_y = \frac{K_1}{T}\int_0^T i_2 \phi_{m1} dt$$

$$= \frac{K_1}{T}\int_0^T I_{max}\Phi_{max} \sin^2 \omega t dt$$

$$T_y = K_1 \frac{I_{max}\Phi_{max}}{2} = K_1 I \Phi$$

where

T_y = average torque at full scale deflection
I = rms current at full scale deflection
Φ = rms mutual flux at full scale deflection

$$T_y = \frac{(IN)}{981}\frac{4}{\pi}\Phi \tag{5}$$

$$\Phi = T_y \frac{981}{NI}\frac{\pi}{4} \tag{6}$$

Determination of Effective Oil Temperature in a Transformer

MARTIN F. BEAVERS
MEMBER AIEE

TOP oil temperature and winding temperature by resistance are determined by direct measurements when a heat run is made on a transformer in accordance with the American Standards Association Test Code[1] for transformers. However, the average oil* temperature is not directly measureable. The test code states that the average oil temperature may be approximated by subtracting one-half of the tank temperature gradient (as determined by measurement of the temperature at the top and bottom surfaces of the external cooling means) from the top oil temperature.

Since it is the oil immediately surrounding the windings which cools the windings, it is logical to assume that if the load on the transformer is suddenly reduced to zero, the windings will immediately begin cooling to the temperature of the surrounding oil which is effectively cooling the winding. In other words, the effective oil temperature is the temperature to which the winding is cooling at the instant of shutdown of a heat run.

This paper shows how the data obtained in taking several hot-resistance measurements on the windings immediately following shutdown of a continuous heat run on a transformer can be used to determine the effective oil temperature and time constant of each individual winding, as well as the winding temperature at instant of shutdown.

This paper also gives the results of analysis of heat runs on several transformers. The study shows that the average oil temperature as determined in accordance with the Test Code is in fairly close agreement with the effective oil temperature obtained from the resistance-time data methods as described herein.

If the true effective oil temperature is established by one of these methods, it is very probable that a developmental investigation will show that a simple system of tank and/or cooling-tube temperature measurements may be used to calculate the effective oil temperature more directly.

In this respect, the methods are offered as useful tools in the search for a better understanding of transformer thermal characteristics.

Resistance-Time Cooling Curve of Winding

One of the methods recognized by American Standards Association[1] in obtaining the temperature of windings at instant of shutdown is to take several hot-resistance readings at different time intervals. By plotting this resistance-time data on linear co-ordinate paper and extrapolating back to zero time (instant of shutdown), the resistance at instant of shutdown may be obtained. The winding temperature at shutdown is then determined from this value of resistance.

If the first of several hot-resistance readings on a winding is sufficiently close to the instant of shutdown to permit accurate extrapolation of the cooling curve back to zero time, the resistance (R_0) at instant of shutdown may be determined quite accurately as shown by the high-voltage coil curve in Figure 1.

If, however, the cooling curve must be extrapolated from two or three minutes back to shutdown, the value of R_0 is subject to an appreciable error by this method as illustrated by the dashed part of the low-voltage coil curve in Figure 1. For such cases, two alternate methods are suggested later for a more accurate determination of the value of R_0.

Windings Cool Exponentially

It has been well established[2,3,4] that windings cool in accordance with the general relation

$$K\theta^n dt = -Cd\theta \qquad (1)$$

where

θ = temperature rise of winding over oil at any time t after start of cooling period
K = heat transfer coefficient, winding to oil
t = time after start of cooling
C = heat storage capacity of winding

If a winding cools linearly as a function of the heat loss, the solution of this equation is

$$\theta = \theta_0 e^{-t/\tau} \qquad (2)$$

where θ_0 is the winding rise over oil at start of cooling period and τ is the time constant of the winding.

If a winding cools as a function of (loss)^n, where n is any value other than 1, the solution of equation 1 is

$$\theta = \theta_0\left[1+(n-1)\frac{t}{B}\right]^{-\frac{1}{n-1}} \qquad (3)$$

where $B = \theta_0 C/K\theta_0^n$

After analyzing the resistance-time data on several different types of transformers, it was concluded that when the value of n was not over about 1.25, the results using equation 2 were sufficiently accurate to justify the use of equation 2 in the majority of the cases analyzed. Equation 2 lends itself to relatively simple mathematical manipulation and permits a satisfactory solution whereas the solution by equation 3 may be extremely difficult.

For these reasons, the methods pre-

Paper 50-112, recommended by the AIEE Transformers Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE North Eastern District Meeting, Providence, R. I., April 26–28, 1950. Manuscript submitted January 23, 1950; made available for printing February 27, 1950.

MARTIN F. BEAVERS is with the General Electric Company, Pittsfield, Mass.

Figure 1. Resistance-time cooling curves of windings having exponential decay characteristics

Figure 2. Resistance increment, ΔR, versus time t, for windings which cool exponentially, plot as a straight line on semilogarithmic co-ordinate paper

sented in this paper assume that all windings cool in accordance with equation 2.

Since resistance changes are directly proportional to temperature changes, the differential ΔR between the hot resistance R and the resistance R_e to which the winding is cooling at instant of shutdown will vary exponentially, that is,

$$\Delta R = R - R_e = \Delta R_o e^{-t/\tau} \qquad (4)$$

where R_e, called hereafter "effective resistance," is the resistance corresponding to the effective oil temperature.

ΔR_o is the resistance differential at instant of shutdown, that is, $\Delta R_o = \Delta R$ when $t=0$, or $\Delta R_o = R_o - R_e$ where R_o is the hot resistance at instant of shutdown.

Exponential Curve Plots as Straight Line on Semilogarithmic Co-ordinate Paper

Any data having an exponential relationship will plot as a straight line on semilogarithmic co-ordinate paper.[3,4]

As an illustration, consider the case of a hypothetical transformer having the characteristics shown in Table I.

From the data shown in Table I, the relation of ΔR and t may be tabulated as shown in Table II.

These data are plotted on semilog paper as shown in Figure 2 and it will be observed that all of the points fall on a straight line. Extrapolating the lines back to zero time, the value of ΔR_o for both high-voltage and low-voltage windings is observed to be 0.0476 which, when added to $R_e = 0.9524$, results in the value of $R_o = 1.0000$ (the originally assumed value of the shutdown resistance).

This illustrates, therefore, that the resistance differential (ΔR) versus time (t) of a winding which cools exponentially will plot as a straight line on semilog co-ordinate paper if the values of R and R_e are accurately determined.

Table I

	High Voltage	Low Voltage	Top Oil	Eff. Oil
Temperature rises, degrees centigrade	55.0	55.0	45.0	40.0*
Time constant of winding*, minutes	10.0	..	5.0	
Resistance measurements:**				
Cold (at 25 C)	0.8250		0.8250	
Hot resistance (R),				
At 1 minute†	0.9955			
At 2 minutes	0.9843			
At 3 minutes	0.9877			
At 4 minutes	0.9738			
At 5 minutes	0.9813			
At 6 minutes	0.9668			
At 7 minutes	0.9761			
At 8 minutes	0.9620			
At 10 minutes	0.9609			

*The time constants and effective oil temperature are normally unknown, but for the purpose of establishing data for the hypothetical transformer, the values shown were used. The solution of the problem should result in these values.

**All resistance values are calculated on the basis of $R_o = 1.0000$ at 80 degrees centigrade (=55 degree-centigrade rise+25 degree-centigrade ambient). Hot resistance values are calculated according to the relation $R = (\Delta R + R_e)$ where $R_e = 0.9524$ that is, R_e is the resistance corresponding to 65 degrees centigrade (=40 degree-centigrade rise+25 degree-centigrade ambient) effective oil temperature and $\Delta R = \Delta R_o e^{-t/\tau}$. In this case, $\Delta R_o = (1.0000 - 0.9524) = 0.0476$.

†The resistance-time data are plotted in Figure 1.

Determination of Effective Oil Temperature and the Resistance R_e at Shutdown

For the purpose of the illustrative hypothetical transformer just described the value of effective resistance R_e was known to be 0.9524. However, the resistance-time data taken immediately at the termination of a heat run do not immediately disclose the value of R_e. In fact, it is this value which is to be determined.

As indicated previously, the basic assumption in this paper is that a winding cools exponentially from its temperature at instant of shutdown to the mean temperature of the oil which is effectively cooling the winding at the time of shutdown. Since the oil temperature change very slowly after the load is removed very little change will occur during the

Figure 3 (left). Resistance increment, ΔR, versus time t for various values of effective resistance, R_o. Time constant is 5.0 minutes

Figure 5 (right). Graphical determination of the time constant τ of a winding. See text for $f(\tau)$

five to ten minutes usually required to obtain several hot-resistance readings on the windings.

Proceeding on this basic assumption, it is only necessary to find, by trial and error, the value of R_o which, when subtracted from the various values of R, will produce a straight-line plot of ΔR $(=R-R_o)$ versus time (t) on semilog paper.

Such a procedure is illustrated in Figure 3 for the low-voltage winding resistance-time data of the hypothetical transformer referred to previously. Assume, for example, that the first selection of a value of R_o is 0.9550. A plot of ΔR versus t on semilog paper is shown by curve 1. It will be observed that the points in the long-time region are below a straight line drawn through the two points nearest zero time. This indicates that the value of R_o is too high. Now assume that $R_o=0.9500$ is chosen. The plot of ΔR versus t for this value is shown by curve 3. It will be observed that the points in the long-time region are now above the straight line through the first two points, indicating that the value of R_o is too low. The correct value of R_o is obviously between 0.9500 and 0.9550. Another try or two will show that a value of $R_o=0.9524$ will cause all of the points to lie on a straight line, indicating that 0.9524 is the correct value of R_o.

It is interesting to observe that even with a relatively large change in value of R_o, the value of R_0 (the resistance at instant of shutdown) is not greatly in error. For example, curve 1 in Figure 3 gives a value of $\Delta R_0=0.0456$ and $R_0=0.9550+0.0456=1.0006$, while curve 3 gives a value of $\Delta R_0=0.0493$ and $R_0=0.9500+0.0493=0.9993$, whereas the correct values from curve 2 are $\Delta R_0=0.0476$ and $R_0=0.9524+0.0476=1.0000$.

Referring to the usual linear plot of R versus t shown in Figure 1, the dashed

*In case of short-circuit tests, top oil and effective oil temperature was determined at end of normal current run only.

**Average of high-voltage and low-voltage values.

†Top oil temperature minus one-half the tank gradient.

curve for the low-voltage winding illustrates that a value of $R_0 = 0.9970$ might result from a long extrapolation of the plot back to zero time.

It should be pointed out that for the sake of accuracy, the hot-resistance readings should be taken over a period of time approximately as long as the time constant of the winding under test.

For example, if the time constant of a winding is 30 minutes, resistance readings out to only eight or nine minutes will result in a straight-line plot of ΔR versus t on semilog paper for a wide range of values of R_e. This is illustrated in Figure 4. It will be observed, however, that readings plotted at 12 minutes will more definitely indicate the correct value of R_e. Readings at 20 to 30 minutes will give even better results.

When resistance readings have to be taken over a very long period, consideration must be given to the drop in effective oil temperature which will occur during the extended period of readings. In other words, if the oil temperature is one degree lower at the time a certain value of hot resistance is obtained, this resistance reading should be corrected to a value corresponding to one degree higher temperature. Thus, all of the hot-resistance values so obtained will correspond to the condition of a constant oil temperature.

It has been observed that the effective oil temperature changes very nearly the same amount as the top oil temperature, therefore correction for change in effective oil temperature may be made in accordance with top oil temperature changes during the period of taking extended resistance-time data.

Two other methods are given in Appendix for the determination of R_e. Both of these methods require a precise determination of the shutdown resistance R^0.

Two alternative methods are also given in the Appendix for the determination of R_0 which may be useful when a long extrapolation of the usual resistance-time plot on linear co-ordinate paper might give chance to an appreciable error in R_0.

Knowing the correct value of R_e, the effective oil temperature T_e may be determined from the relation

$$T_e = \frac{R_e - R_c}{R_c}(T_c + 234.5) + T_c \qquad (5)$$

where R_c is the "cold" resistance measured at temperature T_c.

It should be pointed out that all of these methods require the use of resistance values to at least the fourth significant figure (for example, 186.6, 11.17, 0.9726, or 0.007562) because the differences in the equations are usually small and the last figure in the difference may be a fair percentage of the result (for example, $0.9844 - 0.9726 = 0.0118$ but $0.984 - 0.973 = 0.011$).

Needless to say, any method employed in the accurate determination of the effective resistance R_e and the resistance R_0 at instant of shutdown requires that the data be accurate. One constant source of error is the possible effect of induction which is inherent when direct current is applied to an inductance coil. Errors due to this and other causes have been detected when the resistance-time data were plotted on graph paper as shown in Figure 1. If one point on the plot appears to be out of line, the results will be much more reliable if that point is ignored and data for computations taken from the curve itself which is the mean of all of the data.

Determination of Time Constant of Individual Windings from Test Data

The time constants of the windings may be determined by means of the data in Figure 2. As is well known to those who are familiar with exponential curves, the time constant is the time required for the coil to cool to 36.8 per cent of its ultimate change—in this case to 0.368 ΔR_0. Therefore, the time corresponding to the value of 0.368 ΔR_0 is the time constant. In the case of the hypothetical transformer curves shown in Figure 2, $0.368 \times 0.0476 = 0.0175$. The time constants of the high-voltage and low-voltage windings, as determined from these curves, are τ (high voltage) $= 10.0$ minutes and τ (low voltage) $= 5.0$ minutes, which are the originally assumed values.

The time constant also may be determined by substituting the correct value of R_e in the equation

$$\tau = \frac{0.434t}{\log \dfrac{R_0 - R_e}{R - R_e}} = \frac{0.434t}{\log \dfrac{\Delta R_0}{\Delta R}} \qquad (6)$$

For the case just cited, τ for the high-voltage coil is

$$\tau = \frac{0.434 \times 5}{\log \dfrac{0.0476}{0.0289}} = \frac{2.170}{\log 1.65} = 10.0 \text{ minutes}$$

It may be shown that, for a winding which cools exponentially

$$f(\tau) = K_1 e^{-x} - K_2 e^{-y} + (K_2 - K_1) \qquad (7)$$

where

$K_1 = R_1 - R_2$

$K_2 = R_1 - R_3$

$x = \dfrac{t_2 - t_1}{\tau}$

$y = \dfrac{t_3 - t_1}{\tau}$

By assuming various values of τ in the exponents x and y, various values of $f(\tau)$ will be obtained. The correct value of τ is obtained when $f(\tau) = 0$.

As an illustration of this method, data taken from the low-voltage coil of the hypothetical transformer is as follows:

$R_1 = 0.9843$ $\quad t_1 = 2$ minutes
$R_2 = 0.9738$ $\quad t_2 = 4$ minutes
$R_3 = 0.9620$ $\quad t_3 = 8$ minutes
$K_1 = 0.9843 - 0.9738 = 0.0105$
$K_2 = 0.9843 - 0.9620 = 0.0223$

τ	$f(\tau)$
4	0.000617
5	0.000004
6	−0.000316

These data are plotted as shown in Figure 5. It will be observed that $\tau = 5.02$ minutes where $f(\tau) = 0$ on the graph. The correct value is 5.0 minutes.

Knowing τ, solve for ΔR_0 from the relation

$$\Delta R_0 = \frac{R_1 - R_2}{e^{-t_1/\tau} - e^{-t_2/\tau}}$$

In the case cited

$$\Delta R_0 = \frac{0.0105}{e^{-2/5} - e^{-4/5}} = 0.0476 \qquad (8)$$

Solve for

$$R_e = R - \Delta R_0 e^{-t/\tau}$$
$$= 0.9843 - 0.0476 e^{-2/5} = 0.9524$$

Transformer Test Data

Resistance-time data taken from heat-run test records on several transformers of various ratings have been analyzed by the methods outlined in this paper and the results on typical ratings are shown in Table III.

It will be observed that the effective oil temperature as determined from the high-voltage coil data is, in most cases, different from the value as determined by the low-voltage coil data. This indicates, as might be expected, that the size of the ventilating ducts, relative position of the windings to each other and to the core, as well as the division of losses in the transformer, may affect the temperature of the oil which effectively cools each individual winding. However, in all cases, the average of the high-voltage and low-voltage values of effective oil agrees very closely to the value obtained by subtracting one-half of the tank gradient from top oil temperature.

Heat runs of the bucking (opposition) type and of the short-circuit type were analyzed. In all of the short-circuit tests, the top oil and effective oil temperatures were determined at the end of the normal current run since resistance readings were normally available only for this condition.

Summary

It has been shown in this paper that:

1. The effective oil temperature and the thermal time constant of each winding, as well as the winding temperature at instant of shutdown, can be determined from the resistance-time data taken immediately after the shutdown of a heat run on a transformer.

2. The average oil temperature as determined in accordance with the Test Code checks, within limits of test accuracy, the effective oil temperature determined by the resistance-time data methods described in this paper.

3. The effective oil temperature for each individual winding may not necessarily be the same value. This indicates that such factors as size of ventilation ducts, relative position of the windings to each other and to the core, and the division of loss in the transformer, may affect the temperature of the oil which effectively cools each individual winding.

Appendix

List of Symbols

θ = winding rise over oil at time t after shutdown of heat run
θ_0 = winding rise over oil at instant of shutdown
e = 2.718
R = hot resistance measured at time t after shutdown of heat run
R_0 = resistance at instant of shutdown
R_e = effective resistance, that is, the resistance corresponding to the effective oil temperature
ΔR = resistance differential, that is, $(R - R_e)$
ΔR_0 = resistance differential at instant of shutdown, that is, $(R_0 - R_e)$
τ = time constant of winding, minutes
t = time after shutdown of heat run, minutes

Determination of Shutdown Resistance R_0

Since a long extrapolation of the resistance-time cooling curve back to zero time may give chance to an appreciable error in the shutdown resistance, R_0, the following two methods are suggested for finding R_0. These two methods assume that the windings cool in accordance with equation 2.

Solve for R_0 in the expression

$$\left(\frac{R_0 - R_1}{R_0 - R_2}\right)^2 = \frac{R_0 - (2R_1 - R_{21})}{R_0 - (2R_2 - R_{22})} \qquad (9)$$

This expression may be reduced to a quadratic of the form $ax^2 + bx + C = 0$, the solution of which is

$$X = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

or

$$R_0 = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a} \qquad (10)$$

where

$a = R_{22} - R_{21}$
$b = R_1(R_1 - 2R_{22}) - R_2(R_2 - 2R_{21})$
$c = R_1^2(R_{22} - 2R_2) - R_2^2(R_{21} - 2R_1)$

and where

R_1 is the hot resistance at time t_1
R_{21} is the hot resistance at time $2t_1$
R_2 is the hot resistance at time t_2
R_{22} is the hot resistance at time $2t_2$

Values of R for various times are taken from the resistance-time cooling curve such as is illustrated in Figure 1. It is desirable, for the sake of accuracy, to select t_1 and t_2 a reasonable time apart.

Rather than solve the above equation for R_0, it may be found more convenient to solve the problem graphically.

Let $A = R_0 - R_1$, $B = R_0 - R_2$
$C = R_0 - (2R_1 - R_{21})$, $D = R_0 - (2R_2 - R_{22})$

Then, for equation 9

$$\left(\frac{A}{B}\right)^2 = \frac{C}{D}$$

Plot two curves, one representing the quantity $(A/B)^2$ and one representing the quantity C/D, as a function of assumed values of R_0, as illustrated in Figure 6. The intersection of the two curves occurs at a value of R_0 which satisfies both quantities and, therefore, is the correct value of R_0.

To illustrate this graphical method, the necessary data are taken from the low-voltage coil curve in Figure 1 and are tabulated as follows:

$R_1 = 0.9843$, $\quad t_1 = 2.0$ minutes
$R_{21} = 0.9738$, $\quad 2t_1 = 4.0$ minutes
$R_2 = 0.9738$, $\quad t_2 = 4.0$ minutes
$R_{22} = 0.9620$, $\quad 2t_2 = 8.0$ minutes

$A = R_0 - R_1 = R_0 - 0.9843$
$B = R_0 - R_2 = R_0 - 0.9738$

$C = R_0 - (2 \times 0.9843 - 0.9738) = R_0 - 0.9948$
$D = R_0 - (2 \times 0.9738 - 0.9620) = R_0 - 0.9856$

$$\left(\frac{A}{B}\right)^2 = \left(\frac{R_0 - 0.9843}{R_0 - 0.9738}\right)^2 \cdot \frac{C}{D} = \frac{R_0 - 0.9948}{R_0 - 0.9856}$$

Substituting various assumed values of R_0 in the foregoing equations, Table IV is obtained.

The curves for R_0 versus $(A/B)^2$ and R_0 versus C/D are plotted in Figure 6. The intersection of these curves occurs at $R_0 = 1.0000$, the correct value.

Determination of the Effective Resistance R_e

The effective resistance, R_e, also may be determined by calculations for windings which cool exponentially. Two methods are suggested as follows:

(1). From equation 4, it can be shown that

$$\frac{1}{\tau} = \frac{2.303}{t_1} \log \frac{R_0 - R_e}{R_1 - R_e} \qquad (11A)$$

Table IV

R_0	$(A/B)^2$	C/D
0.9948	0.250	0
0.9960	0.278	0.115
0.9980	0.320	0.258
1.0000	0.360	0.360
1.0020	0.394	0.439

Figure 6. Graphical determination of the resistance R_e at instant of shutdown. See text for A, B, C, and D

Figure 7. Graphical determination of effective resistance, R_e. See text for Y

$$\frac{1}{\tau}=\frac{2.303}{t_2}\log\frac{R_0-R_e}{R_2-R_e} \qquad (11B)$$

Equating (11A) and (11B), we obtain the relation

$$\frac{t_2}{t_1}=\frac{\log(R_0-R_e)-\log(R_2-R_e)}{\log(R_0-R_e)-\log(R_1-R_e)}=\frac{\log\Delta R_0-\log\Delta R_2}{\log\Delta R_0-\log\Delta R_1}=Y \qquad (12)$$

By substituting various values of R_e in equation 12, a different value of Y will be obtained. Plot R_e versus Y as shown in Figure 7. The value of R_e from this curve, corresponding to $Y=t_2/t_1$, represents the correct value of R_e which satisfies both equations 11A and 11B.

As an illustration of this method, an example is given using the low-voltage winding data of the hypothetical transformer in "Exponential Curve Plots As Straight Line On Semilogarithmic Co-ordinate Paper" of the paper:

$R_0=1.0000$, $R_1=0.9843$, $R_2=0.9738$
$t_1=2.0$ minutes, $t_2=4.0$ minutes.

Prepare tabulation as follows and substitute various values of Re in equation 12. Solve for Y:

R_e	$\Delta R_0 = R_0 - R_e$	$\Delta R_1 = R_1 - R_e$	$\Delta R_2 = R_2 - R_e$	$\log \Delta R_0$	$\log \Delta R_1$	$\log \Delta R_2$	Y
0.9400	0.0600	0.0443	0.0338	0.7782–2	0.6464–2	0.5289–2	0.2493/0.1318 = 1.89
0.9450	0.0550	0.0393	0.0288	0.7404–2	0.5944–2	0.4594–2	0.2810/0.1460 = 1.92
0.9500	0.0500	0.0343	0.0238	0.6990–2	0.5353–2	0.3766–2	0.3224/0.1637 = 1.97
0.9550	0.0450	0.0293	0.0188	0.6532–2	0.4669–2	0.2742–2	0.3790/0.1863 = 2.03
0.9600	0.0400	0.0243	0.0138	0.6021–2	0.3856–2	0.1399–2	0.4622/0.2165 = 2.13

Plot R_e versus Y as shown in Figure 7. The value of R_e corresponding to $t_2/t_1=4.0/2.0=2.0$ is found to be 0.9525. 0.9524 is the correct value.

(2). The maximum change in hot resistance (ΔR_0) in cooling from the resistance of the winding at instant of shutdown (R_0) to the resistance corresponding to the effective oil temperature (R_e) is

$$\Delta R_0=(R_0-R_e)=\frac{R_0-R_1}{2-\dfrac{(R_0-R_2)}{(R_0-R_1)}} \qquad (13)$$

where R_1 is the resistance at time t_1 from instant of shutdown and R_2 is the resistance obtained from the resistance-time cooling curve at time $2t_1$.

To illustrate this method, the resistance-time cooling curve for the high-voltage winding in Figure 1 will be used. From this curve, the following data are obtained:

$R_0=1.0000$, $R_1=0.9877$ at $t_1=3.0$ minutes
$R_2=0.9786$ at $2t_1=6.0$ minutes

Substituting these values in equation 13

$$\Delta R_0=\frac{1.0000-0.9877}{2-\dfrac{(1.0000-0.9786)}{(1.0000-0.9877)}}=\frac{0.0123}{2-\dfrac{0.0214}{0.0123}}=\frac{0.0123}{0.260}=0.0473$$

$R_e=R_0-\Delta R_0$, therefore, $R_e=1.0000-0.0473=0.9527$ which is in close agreement with the correct value of 0.9524.

The effective resistance also may be obtained by the trial and error method suggested in "Determination of Effective Oil Temperature and the Resistance R_0 at Shutdown" of the paper for the determination of R_e. This method also may be used as a check on the accuracy of the value of R_e obtained from methods (1) or (2) above.

Discussion

Paul Narbutovskih (Westinghouse Electric Corporation, Sharon, Pa.): The average temperature of transformer oil has been, in a certain sense, a subject very much like the weather: it has been frequently mentioned mostly as a somewhat hypothetical quantity, but very little has been done about it. It is a quantity elusive of experimental determination, and yet it is of considerable theoretical and practical importance in view of the fact that the recognized and the most reliable measurement of the copper temperature by resistance yields the average temperature result. Because of this, the paper by Mr. Beavers is certainly a welcome addition to the literature on the subject. A reliable and a practically simple method of determining average oil temperature by test

will go a long way toward ascertaining the thermal characteristics of a transformer.

The definition itself of the average oil temperature does not as yet appear to be sufficiently clear cut. It is natural that a practical definition of a physical quantity should be dependent upon the method available for its measurement. Since the average oil temperature in a transformer appears to be measurable as the limiting average temperature of copper after time of shutdown, this may well be accepted as the workable definition for the average oil temperature, at least for the purpose of determining a true winding to oil gradient. It must be appreciated, however, that the temperature thus defined will not be entirely adequate for other purposes, such as estimating the heat loss from transformer cooling surfaces.

In establishing any new method of measurement, the weight of experimental data is of prime importance. The writer has analyzed a considerable number of cooling curves of the transformer windings. The results, with possibly a few exceptions, are in agreement with the basic proposition stated in Mr. Beavers' paper, namely that transformer windings cool approximately according to an exponential law

$$\theta = \theta_0 \epsilon^{-t/\tau} \tag{1}$$

where

θ = temperature difference between average winding and average oil temperature at time t, minutes after shutdown

θ_0 = initial temperature difference, as above, at time of shutdown (average winding gradient)

τ = time constant of the winding, minutes

ϵ = base of natural logarithms

The method of analysis used by the writer was, however, somewhat different from that used by Mr. Beavers, and since it seems to have certain advantages, it is presented below along with some of the experimental data.

After the resistance values versus time after shutdown are obtained, instead of plotting the difference $(R-R_e)$ versus time on a semilog paper for different values of R_e—a time consuming operation, the resistance value R is directly plotted versus ratio t/τ on an exponential transient coordinate paper.[1] Since the value of the time constant τ is not known, a convenient figure may be chosen for τ, such as 5, 10, or 20 minutes. If the chosen value of τ were equal to the time constant of the winding, the plot would be approximated by a straight line. Generally, however, a considerable deviation from a straight line will exist as shown by curves A and B of Figure 1 of the discussion, of which the first one is plotted for $\tau=10$, and the second is plotted for $\tau=5$ minutes. Two such curves can be extrapolated with a fair accuracy to the time of shutdown $(t/\tau=0)$, and to time when the ultimate winding temperature (that is, average oil temperature) is reached $(t/\tau=\infty)$, taking advantage of the fact that the terminal points of all such curves are the same.

In many cases, after the curves A or B are drawn, no second approximation will be necessary. If such is desired, however, it may be determined without any random guessing at the proper value of τ required to give a straight line plot of the data. Using a straight edge laid between the first approximations of points R_0 and R_e Figure 1 and Figure 2, two values of the abscissa t/τ are noted for some convenient value of resistance R, for example, X and X_1 of which X belongs to one of the curves, while X_1 belongs to the straight line. The correct second approximation for the copper time constant, τ_1, is then calculated as

$$\tau_1 = \tau \frac{X}{X_1} \tag{2}$$

The above procedure applied to the data on Figure 1 of the discussion results in the value of the time constant $\tau=7.43$ minutes and curve C. It may be noted that the latter is not quite a straight line, indicating that the transient change in the copper temperature does not exactly conform to the exponential law. However, using this plot an extrapolation of the curve to the terminal points is probably as accurate as the original test data.

Most of the cooling curves of copper examined by the writer deviate somewhat from the exponential law, some quite appreciably. Relatively few behave in such a well-trained manner as the example given by Mr. Beavers or that given in Figure 1. In view of this the test data should extend for a period of time equal to about twice the time constant of the winding and preferably even longer. If the deviation from an exponential curve is present, the use of data extending over a period of one time constant, or less, may lead to a considerable error in the determination of the ultimate temperature of the cooling copper. This, of course, is also true when the semilog paper, or an analytical method, is employed, such as is described by Mr. Beavers, since, in this case, one must rely on a long range extrapolation, using an assumed law which may not and usually does not apply.

For accurate results a correction is required in the values of the copper resistance to compensate for any appreciable drop in the oil temperature during the test. A precise theoretical correction required is difficult to make. A reasonably accurate correction can be simply made, however, if it is assumed that the oil temperature drops linearly with time after shutdown, at least for the limited duration of the test. Furthermore, it may be assumed that the nature of the rapid transient in the copper to oil temperature differential is not affected by the relatively slow change in the oil temperature. On these assumptions the correction to be added to the experimental values of resistance may be calculated by

$$\Delta R = \frac{R_e t}{234.5+\theta_e}\left(\frac{d\theta}{dt}\right) \tag{3}$$

where

ΔR = additive correction for the test resistance values

R_e = cold winding resistance at temperature θ_e

$\frac{d\theta}{dt}$ = rate of oil temperature change during the test, degrees centigrade per minute (Top oil temperature measurements may be used)

t = time after shutdown, minutes

This correction is rather important, and even as few as $1^1/_2$- or 2-degrees centigrade oil temperature change during the test, if neglected, may lead to an appreciable error in the windings temperature gradient to oil and its time constant.

The writer had a chance to verify the foregoing method on transformers with forced circulation of oil. In many cases the oil turnover is so rapid that there is only a small temperature differential between the incoming and outgoing oil, and it may be safely assumed that the average oil temperature is equal to the arithmetic mean of the two. Applied to these transformers the method of determining the average oil temperature just described, gave results agreeing very closely with the oil temperature measured by thermocouples. As an example, in Table I of the discussion values

Table I. Values of Oil Temperature, Degree Centigrade

	Winding Number	Average Oil, θ_e	Mean Oil, In and Out of Coolers
167 per cent load	1	64	63.5
	2	65.5	66
	3	65	62
	4	61.5	62.5
133 per cent load	1	65.4	64
	2	60.5	61.5
	3	62.5	60.5
	4	64	62.5
100 per cent load, self-cooled	1	59	57.1
	3	53.5	52.5

are given obtained on a 25,000-kva shell form transformer, enclosed in a form fit tank.

In the 100 per cent load heat runs given in Table I, an appreciable difference between top and bottom oil temperature existed. Nevertheless, the mean value

Figure 1. Variation of winding resistance in a 1,000-kva, forced air transformer, plotted versus ratio t/τ on an exponential coordinate paper

seems to be in a good agreement with the average oil temperature determined as an asymptotic average temperature of the cooling copper.

REFERENCE

1. SIMPLIFIED GRAPHICAL METHOD OF COMPUTING THERMAL TRANSIENTS, P. Narbutovskih. *AIEE Transactions*, volume 66, 1947, pages 78–83.

Andrew Hvizd, Jr. (Yonkers, N. Y.): The method proposed for determining the effective oil temperature shows possibilities of being useful not only for developmental investigations as mentioned in the paper, but also for commercial heat-run tests.

Having used this method on several heat-run tests, I should like to stress that the resistance readings taken at the culmination of a heat run be extended to a period of time greater than $1^1/_2$ times the time constant of the winding for the best results. An extension of these readings to 1/2-hour would suffice in the majority of cases.

It is specified in the paper that this method is most applicable in those instances where the n of the equation 3 is less than 1.25. Ordinarily, the value of n is unknown. Consideration should be given to a modification of the proposed method to cover all possible values of n. This could be done by observing the characteristic manner into which the test points will align themselves on semilogarithmic co-ordinate paper for values of n greater than 1.25, and some sort of criterion devised which would select the correct value of R_e. As it stands, there is no indication of the accuracy of the results while n remains unknown.

M. F. Beavers: The method suggested by Mr. Narbutovskih of plotting the resistance values of R versus the ratio of t/τ on a special exponential co-ordinate paper illustrates an interesting version of the same basic idea presented in my paper. As may be seen from equation 4 of the paper, $R = R_e + (R_0 - R_e)^{-t/\tau}$. This may be rearranged to $R = R_0 - (R_0 - R_e)(1 - \epsilon^{-t/\tau})$. By constructing the scale on the abscissa as a function of t/τ in the expression $(1 - \epsilon^{-t/\tau})$ the resistance of a winding which cools in accordance with equation 1 of the discussion will plot as a straight line on this co-ordinate paper.

For those cases where the winding cools as a function of (loss)^n, where n is any value other than 1, the cooling data will not, as pointed out by Mr. Narbutovskih and Mr. Hvizd, plot as a straight line on semilog paper. This also is true for such data plotted on the co-ordinate paper suggested by Mr. Narbutovskih. If the value of n is not substantially different from 1, the deviation of the data from a straight line in either case will not, for practical purposes, be serious. However, when n is substantially different from 1, it is necessary, as suggested, to take hot-resistance readings for a period of time equal to twice or three times the time constant of the winding. I have found that readings extending over a 30-minute period after shutdown is usually sufficient in the majority of cases.

The correction suggested by Mr. Narbutovskih in equation 3 of his discussion is essentially the same as was used by the author in correcting for drop in oil temperature during the extending period when hot-resistance readings were being taken.

Mr. Hvizd comments on the fact that the value of n in equation 3 of the paper is usually unknown for the particular winding under consideration. This is, to some degree, true. However, a little experience with this method will indicate the characteristic manner in which the points align themselves for different values of n, and as more test data are analyzed, the correct value of n for various types of windings will be obtained.

Transverse Flux Induction Heating

ROBERT M. BAKER
MEMBER AIEE

For several years following 1941, the author was engaged in the development of radio-frequency induction heating for the flow-brightening of electrolytic tin plate. In this method, the steel strip (approximately 0.01-inch thick and 30 inches or more wide) is passed through rectangular helical copper coils supplied with radio-frequency (approximately 200 kc) currents. Lines now are in operation melting the electrolytically-deposited tin coating at speeds of 1,300 feet per minute, with a power input of 1,200 kw to the strip. This method of induction heating will be called longitudinal flux induction heating because the magnetic flux is directed along the length (longitudinal to) the strip.

During the early stages of this development, it was recognized that an equally large potential field of application for induction heating existed in the heating of nonferrous strip like aluminum, brass, copper, and magnesium. It also was soon realized that longitudinal flux heating, so admirably suited to the heating of magnetic steel strip, was not satisfactory for heating nonferrous strip or stainless steel strip which does not have ferromagnetic properties. Reasoning that the limitations of longitudinal flux heating were due to the fact that the small cross-section of the nonferro-magnetic strip intercepted only a very small percentage of the flux through the inducing coil, a special method of induction heating was devised to overcome this difficulty. The method will be called transverse flux induction heating because magnetic flux is directed perpendicular to the surface and through the strip instead of along its length, as in longitudinal flux heating. Although this method of heating has not been publicized, two 300-kw pilot line installations have been made.

It is the purpose of this paper to describe the method of transverse flux heating, and to provide a mathematical analysis sufficient for design and application.

Description of Method

Transverse flux heating is accomplished by passing the strip between two opposing laminated pole structures such as shown in Figure 1. The field coils supplied with alternating current are so polarized that at any instant opposing poles have opposite sign and force flux through the strip. From the analysis to follow, it will become evident that the frequency and geometry of the pole structures will depend on the physical and electrical properties of the strip to be heated. A pole structure and coil assembly of a 300-kw 60-cycle installation is shown in Figure 2. This was designed and used to heat aluminum strip 0.040-inch thick and 54 inches wide. Frequencies used in transverse flux heating will range from 60 cycles to 10,000 cycles. The first experimental coil built and tested in 1943 was designed to operate at a frequency of 10,000 cycles and is shown in Figure 3.

The alternating magnetic field through the strip causes voltage to be generated in the strip, and currents flow to heat it. As shown in Figure 4, the currents in the strip tend to concentrate under stator slots, and if the strip is stationary, overheating will occur in these regions. Any point in a moving strip, however, moves through the various regions of current concentration and the averaging effect results in uniform heating of the strip, except near the edges. Special compensation must be provided to obtain uniform heating out to the edge of the strip, as will be explained later.

Quantitative Considerations

One could, of course, arbitrarily choose a pole structure, wind coils into the slots, and apply various frequencies to see what heating effects were obtained in a given strip, but this would obviously not be a practical or desirable procedure. It is necessary to analyze the effect of such variables as air-gap, slot dimensions, pole pitch, strip thickness and resistivity, and frequency to arrive at formulas from which an optimum design can be made.

The writer has chosen a rather formal approach to this problem, and one versed in the mathematics of skin effect will see great similarity between equations derived for transverse flux heating and those currently used to calculate longitudinal flux heating effects.

Figure 1. Pole structure and flux path transverse flux heating

Paper 50-113, recommended by the AIEE Electric Heating Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE North Eastern District Meeting, Providence, R. I., April 26–28, 1950. Manuscript submitted January 26, 1950; made available for printing March 2, 1950.

Robert M. Baker is with the Westinghouse Electric Corporation, Baltimore, Md.

A definition of terms and units is included in the paper. The centimeter-gram-second system of practical units will be used, and all sinusoidally varying quantities like current, voltage, magnetizing force, flux-density, and total flux will be represented as vector quantities.

Basic Assumptions and Equations

To simplify the mathematical calculations, the following assumptions are made. (See Figure 5).

1. Because of symmetry, conditions under only one pole pitch need be considered.
2. Lines of flux in the air-gap are straight lines perpendicular to the pole faces and to the surfaces of the strip.
3. The current paths are as shown in Figure 5(B). This neglects edge effect and is justified because corrective measures must be taken in practice to obtain uniform heating.
4. The discontinuity due to slot openings can be neglected.
5. The strip is equal in width to the pole structures.
6. The magnetic drop in the steel pole structure may be neglected.
7. There is one field coil of (T_c) turns on each pole. The magnetomotive force of two of these coils is therefore active across the air-gap between each pair of poles.

On the basis of these assumptions, conditions are ideally represented in Figure 5 and one may proceed as follows:

The flux through the rectangle $ABCD$ is

$$\phi = 2b\int_0^x \boldsymbol{H}dx \tag{1}$$

The voltage induced around the loop $ABCD$ is

$$\boldsymbol{E} = -j\omega\phi 10^{-8} \tag{2}$$

The current density at distance (x) from the center of the pole pitch is

$$\boldsymbol{I} = \frac{-j\omega\phi 10^{-8}}{2b\rho} = \frac{-j\omega 10^{-8}}{\rho}\int_0^x \boldsymbol{H}dx \tag{3}$$

Differentiating equation 3 gives

$$\frac{d\boldsymbol{I}}{dx} = -j\frac{\omega \boldsymbol{H} 10^{-8}}{\rho} \tag{4}$$

Another equation relating ($\boldsymbol{I}$) and ($\boldsymbol{H}$) is

List of Symbols

DIMENSIONS

b = width of pole structure or strip, both assumed equal, centimeters
l = pole pitch, centimeters (See Figure 4)
s = width of slot, centimeters (See Figure 10)
h = depth of slot, centimeters (See Figure 10)
g = air-gap, centimeters (See Figures 5 and 10)
t = strip thickness, centimeters
x = a variable distance, centimeters (See Figures 5 and 10)
x_0 = half pole pitch, centimeters

MISCELLANEOUS

T_c = number of turns in field coil
ρ = electrical resistivity of strip, ohm centimeters
j = operator $\sqrt{-1}$
k = a parameter defined under equations 7 and 9
f = frequency (cycles per second)
θ_1 = internal power-factor angle (See equation 24)
θ_0 = terminal power-factor angle (See Figure 11)
$M(kl)$ = a function of (kl) (See equation 22)
$N(kl)$ = a function of (kl) (See equation 22)
$F(kl)$ = a function of (kl) (See equation 20)
R_1 = apparent resistance of a field coil produced by air-gap flux, ohms
R_2 = ohmic or self-resistance of field coil including iron loss, ohms
X_1 = apparent reactance of a field coil produced by air-gap flux, ohms
X_2 = slot leakage reactance of a field coil, ohms
$\omega = 2\pi f$
A = a constant of integration
B = a constant of integration
P = power input to strip per pole pitch, watts
W_a = average power density generated in strip, watts per cubic centimeter
f_0 = optimum frequency, cycles per second (See equation 39)

Figure 2 (left). 300-kw 60-cycle transverse flux coil (one pole structure)

Figure 3 (right). Laboratory model 10,000-cycle transverse flux coil

$$\frac{dH}{dx} = -\frac{0.4\pi I t}{g} \tag{5}$$

Differentiating equation 5 gives

$$\frac{d^2H}{dx^2} = -\frac{0.4\pi t}{g}\frac{dI}{dx} \tag{6}$$

VECTOR QUANTITIES

All sinusoidally varying quantities are represented as vectors with a magnitude equal to the peak value of the sinusoidally varying quantity. Absolute values of the vector quantities are represented in the conventional manner. For example, the absolute value of magnetizing force (H) is represented as H.

I_e = current in a field coil, amperes
H = magnetizing force at any point in the air-gap, oersteds
H_0 = magnetizing force at the edge of a pole pitch, oersteds
H_s = magnetizing force at any point in a slot, oersteds
I = current density at any point in the strip, amperes per square centimeter
I_0 = current density in the strip at the edge of a pole pitch, amperes per square centimeter
ϕ = total flux, Maxwell's
ϕ_0 = total air-gap flux per pole pitch, Maxwell's
$-E_t$ = voltage generated in a field coal by air-gap flux, volts
E_1 = component of total applied coil voltage resulting from air-gap flux, volts
E_s = component of total applied coil voltage resulting from slot leakage flux, volts

Eliminating I between equations 4 and 6 gives

$$\frac{d^2H}{dx^2} - j2k^2H = 0 \tag{7}$$

where

$$k = \sqrt{\frac{4\pi^2 f 10^{-8}}{\rho g}}$$

Differentiating equation 4 gives

$$\frac{d^2I}{dx^2} = -\frac{j\omega 10^{-8}}{\rho}\frac{dH}{dx} \tag{8}$$

Eliminating H between equations 5 and 8 gives

$$\frac{d^2I}{dx^2} - j2k^2I = 0 \tag{9}$$

where

$$k = \sqrt{\frac{4\pi^2 f 10^{-8}}{\rho g}}$$

Equations 7 and 9 are the basic equations which, with the proper boundary conditions inserted, can be used to calculate current density distribution in the strip, magnetizing force in the air-gap, total flux over a pole pitch and all the other quantities and relationships needed for a complete analysis of the problem.

Distribution of Flux Density and Current Density

The magnetizing force at any point in the air-gap is the resultant of the magnetizing effect of the field coils and of the circulating currents in the strip. The effect of the circulating currents in the strip is predominantly opposed to that of the field coils, so the net magnetizing force and flux density toward the center of the pole pitch will be less than it is near the edges of the pole pitch. In fact, at the extreme edges of the pole pitch there is no effect from the currents in the strip and the magnetizing force is simply the value H_0 produced by the field coils acting across the air gap, g.

$$H_0 = \frac{0.4\pi(2T_c)I_e}{g} \tag{10}$$

The general solution of equation 7 is

$$H = Ae^{(1+j)kx} + Be^{-(1+j)kx} \tag{11}$$

Since H is an even function of (x) this can be written

$$H = 2A\cosh(1+j)kx \tag{12}$$

Inserting the boundary conditions

$$x = -x_0,\ x = x_0,\ H = H_0$$

one obtains for the magnetizing force at any point in the air-gap

$$H = H_0\frac{\cosh(1+j)kx}{\cosh(1+j)kx_0} \tag{13}$$

The absolute value of magnetizing force determined from equation 13 is

$$H = H_0\sqrt{\frac{\cosh 2kx + \cos 2kx}{\cosh kl + \cos kl}} \tag{14}$$

From this equation, one can plot a family of curves as shown in Figure 6, which shows the variation of H over a pole pitch for various (kl) values. The reader should look closely at the parameter (kl) since it will appear again and again in the following analysis. It is a dimensionless index of the degree of crowding of flux and current toward the edges of a pole pitch. In looking at Figure 6, it helps to visualize what is happening if one assumes that the current in the field coils is held constant to hold H_0 at the edge of a pole-pitch constant, and that the value of (kl) is increased simply by increasing the frequency.

In this case, the curves represent flux-density distribution across a pole pitch for different applied frequencies. Actually, of course, the value of (kl) may vary as a result of varying air-gap, pole pitch,

Figure 4 (left). Current paths in strip-transverse flux heating

Figure 5 (right). Calculation of flux and current density in one pole pitch

Figure 6 (left). Distribution of magnetizing force in air gap

Figure 7 (right). Distribution of current density in strip

strip resistivity, or any of the other factors which it includes.

The general solution of equation 9 will have the same form as equation 11 but since (I) is an odd function of (x), its solution must be written

$$I = 2A \sinh (1+j)kx \tag{15}$$

Inserting the boundary conditions

$x = x_0, I = I_0$ and $x = -x_0, I = -I_0$

one obtains the following equation for the current density in the strip

$$I = I_0 \frac{\sinh (1+j)kx}{\sinh (1+j)kx_0} \tag{16}$$

from which the absolute value of current density is found to be

$$I = I_0 \sqrt{\frac{\cosh 2kx - \cos 2kx}{\cosh kl - \cos kl}} \tag{17}$$

This equation is plotted in Figure 7. Although the relationship is not shown, the ratio of the current density I_0 at the edge of a pole pitch to the magnetizing force H_0 increases rapidly as (kl) increases. The curves of Figure 7 simply show the relative distribution of current density over a pole pitch for various (kl) values. In determining absolute values of (I) and (H) for plotting, the change in phase of these quantities with (x) is lost. The reader may determine phase relationships by going back to equations 13 and 16, but it requires a complicated procedure and adds little or nothing to the understanding of the problem. The author has taken the liberty in Figure 7 of plotting current densities down to the left of the center line and up to the right of the center line. This is not strictly correct, because all are absolute values, but it is done to emphasize the fact that the direction of current flow is predominantly opposite on the two sides.

Field Coil Voltage Due to Air-Gap Flux

The total flux across a pole pitch is

$$\phi_0 = 2b \int_0^{x} H dx \tag{18}$$

Substituting the value of (H) from equation 13 and carrying out the integration gives

$$\phi_0 = \frac{2bH_0}{(1+j)k} \frac{\sinh (1+j)kx_0}{\cosh (1+j)kx_0}$$

which upon expanding, rationalizing, and substituting (kl) for $(2kx_0)$ becomes

$$\phi_0 = \frac{bH_0}{k} \frac{(\sinh kl + \sin kl) - j(\sinh kl - \sin kl)}{\cosh kl + \cos kl} \tag{19}$$

From equation 19 the absolute value of total flux is found to be

$$\phi_0 = blH_0 F(kl) \tag{20}$$

where

$$F(kl) = \frac{\sqrt{2}}{kl} \sqrt{\frac{\cosh kl - \cos kl}{\cosh kl + \cos kl}}$$

The voltage E_1 which must be applied to overcome the voltage induced in a field coil by the air-gap flux is

$$E_1 = j\omega T_c \phi_0 10^{-8} \tag{21}$$

Substituting (ϕ_0) from equation 19 and using H_0 as a reference this becomes

$$E_1 = \omega T_c blH_0 [M(kl) + jN(kl)] 10^{-8} \tag{22}$$

where

$$M(kl) = \frac{1}{kl} \frac{\sinh kl - \sin kl}{\cosh kl + \cos kl}$$

$$N(kl) = \frac{1}{kl} \frac{\sinh kl + \sin kl}{\cosh kl + \cos kl}$$

The absolute value E_1 can be calculated directly from equation 20 and is

$$E_1 = \omega T_c blH_0 F(kl) 10^{-8} \tag{23}$$

The vector relationship of the magnetizing force (H_0), the coil current (I_c), the total air-gap flux (ϕ_0), the induced voltage $(-E_1)$, and the voltage (E_1) are shown in Figure 8. The internal power factor, or the cosine of the angle (θ_1) between the voltage (E_1) and the coil current (I_c) is from equations 22 and 23

$$\cos \theta_1 = \frac{M(kl)}{F(kl)} \tag{24}$$

For ready use in calculations, the functions $F(kl)$, $N(kl)$, and $M(kl)$ are plotted in Figure 9.

Field Coil Voltage Due to Slot Flux

Referring to Figure 10, the magnetizing force across a slot is

$$H_s = \frac{0.4\pi(2T_c)I_c x}{hs} \tag{25}$$

or in terms of the magnetizing force (H_0) across the air-gap at the edge of a pole pitch (equation 10) this becomes

$$H_s = \frac{gx}{hs} H_0 \tag{26}$$

the incremental flux through the cross-section (bdx) is

$$d\phi = bH_s dx \tag{27}$$

The voltage required to overcome the induced voltage in a field coil (2 coil sides in one slot) is

$$dE_2 = \frac{j\omega(2T_c)x(d\phi)10^{-8}}{h} \tag{28}$$

Substituting from equations 26 and 27 and integrating between the limits of zero and (h) gives for the total coil voltage due to slot flux referred to (H_0)

$$E_s = j\omega T_c blH_0 \left(\frac{2hg}{3sl}\right) 10^{-8} \tag{29}$$

It will be noted that this equation is

Figure 8 (left). Internal vector relations of field coil

Figure 10 (right). Field coil voltage due to slot flux

written in a way to show its similarity to equation 22.

The total coil voltage except for the small ohmic resistance drop, which can generally be neglected, is obtained by adding equations 22 and 29.

Resistance and Reactance of a Field Coil—Over-all Efficiency

It is sometimes advantageous to be able to calculate the resistance and reactance of a field coil directly, so equations will be derived for this purpose.

Substituting in equations 22 and 29 the value of H_0 in terms of coil current I_c (equation 10) and dividing the equations by coil current, one obtains expressions for the apparent resistance R_1 and apparent reactance X_1 of a field coil produced by air-gap flux, and the reactance X_2 of a field coil produced by slot flux

$$R_1 = \frac{0.8\pi\omega T_c^2 bl}{g} M(kl) 10^{-8} \tag{30}$$

$$X_1 = \frac{0.8\pi\omega T_c^2 bl}{g} N(kl) 10^{-8} \tag{31}$$

$$X_2 = \frac{0.8\pi\omega T_c^2 bl}{g}\left(\frac{2hg}{3sl}\right) 10^{-8} \tag{32}$$

The self or ohmic resistance R_2 of a field coil can be calculated by conventional methods with due consideration of skin effect when necessary. It is suggested that iron loss in the pole structures be included as an increase in R_2. A total vector diagram for a field coil is shown in Figure 11. Resistance R_2 should always be small in comparison to R_1, X_1, and X_2 and can therefore be neglected in calculating total coil impedance. It is, however, all important in determining efficiency.

The conversion efficiency of the individual coils and therefore that of the over-all coil and core assembly will be

$$\text{Per cent efficiency} = \frac{100R_1}{R_1 + R_2} \tag{33}$$

Figure 9 (below). Functions $F(kl)$, $M(kl)$, and $N(kl)$

Figure 11. Complete vector diagram of field coil

Figure 12. Internal and terminal power factors of field coil

Figure 13. Experimental check of $M(kl)$

Power Density in Strip as a Function of $\overline{H}_1$

Because there are two field coils per pole pitch, the power input to the strip per pole pitch is

$$P = E_1 I_c \cos \theta_1 \tag{34}$$

The average power density in the strip is therefore

$$W_a = \frac{E_1 I_c \cos \theta_1}{blt} \tag{35}$$

Substituting in equation 35 from equations 23 and 24 and expressing (I_c) in terms of (H_0) (equation 10) one obtains the very important equation

$$W_a = \frac{2.5 g f H_0^2}{t} M(kl) 10^{-9} \tag{36}$$

A Good Design

Equations have been derived which permit one to calculate the performance of a transverse flux heating coil given the coil, and the physical and electrical properties of the strip to be heated. Nothing has been said about what constitutes a good design. Common sense and reason permit one to draw general conclusions.

1. The air-gap will usually be the minimum through which the strip can be passed without rubbing.

2. In order to obtain high efficiency, the cross-section of current-carrying conductors in a slot should be as great as possible in comparison to the cross-section of strip (perpendicular to the direction of current flow) under a pole pitch. This is especially important when heating low resistivity material like copper or aluminum.

3. In order to meet condition (2) and at the same time maintain a reasonable ratio of slot-leakage flux to air-gap flux, it is desirable to make the ratio of slot width (s) to pole pitch (l) as large as possible without seriously reducing the flux-carrying area under a pole pitch.

4. In order to minimize the effect of slot reactance, the ratio of slot depth (h) to slot width (s) must not be great.

5. In order to minimize edge effect (principally over-heating at the edges) to the point where it can be corrected by special means, it is desirable that pole pitch (l) be made small in comparison to strip width (b). This condition generally excludes the use of transverse flux for heating narrow strip.

Weighing the foregoing conditions and limitations and drawing on experience, the writer sets forth below some typical ratios of dimensions helpful in approaching a design. These are only guides and may vary somewhat from one design to another.

$$\left.\begin{array}{l} s/g = 1.0 \\ s/l = 0.25 \\ h/s = 2.0 \\ b/l = 4.0 \text{ or greater} \end{array}\right\} \tag{37}$$

From the above, it is seen that the physical dimensions of a pole structure are, to a considerable extent, established when one agrees on an air-gap. The physical and electrical properties of the strip are fixed by the job to be done. The principal unknown remaining to be determined is therefore frequency. How does one then decide what frequency to use? The two obvious criteria are efficiency and terminal power factor.

Assuming a fixed ohmic resistance in a field coil, maximum efficiency will be obtained when the reflected resistance (R_1) is a maximum. From equation 30 and the $M(kl)$ curve of Figure 9, this occurs when $kl = 2.25$, but the peak is broad so that little difference would be expected in efficiency between $kl = 1.75$ and $kl = 3.0$.

In Figure 12 is plotted a curve of internal power factor from equation 24. Also in Figure 12 are shown two curves for terminal power factor. The one is plotted for the condition $hg/sl = 0.5$ which corresponds to the typical ratios of equation 37 or a coil of relatively low leakage reactance. The other is plotted for the condition $hg/sl = 1.0$ which indicates a coil of relatively high leakage reactance. From these curves it is seen that the terminal power factor is maximum for $kl = 2.75$, but again the peak is broad.

It would therefore seem that the frequency determining equation should be $kl = 2.5$ with the understanding that some deviation above or below this value is permissible. Writing this condition

$$kl = 2.5 = l\sqrt{\frac{4\pi^2 f 10^{-9}}{\rho g}} \tag{38}$$

and solving, one obtains an equation for optimum frequency

$$f_0 = \frac{1.58 \rho g}{l^2} 10^9 \tag{39}$$

As mentioned earlier, the required frequency will generally fall in the range between 60 cycles and 10,000 cycles per second. In arriving at a final design, it will be desirable to juggle the dimensions of the pole structure to permit the use of some standard frequency such as 60 cycles, 960 cycles, 3,000 cycles, or 9,600 cycles.

Figure 14. Two coil sides in slot of 60-cycle transverse flux coil

Figure 15. Experimental 300-kw transverse flux heating installation

Experimental Verification of Formulas

After building the small 10,000 cycle coil shown in Figure 3, it was tested with various strips to verify equation 36. All factors in the equation except M (kl) were measured and from these M (kl) was calculated. The resulting curve is shown in Figure 13 marked "Experimental." The theoretical M (kl) curve shown in Figure 9 is reproduced in Figure 13 for comparison. The marked points on the experimental curve correspond to measurements made on the following strips:

1. Lead strip 0.0014-inch thick.
2. Aluminum strip 0.00072-inch thick.
3. Copper strip 0.0011-inch thick.
4. Aluminum strip 0.003-inch thick.
5. Brass strip 0.010-inch thick.
6. Copper strip 0.005-inch thick.
7. Aluminum strip 0.020-inch thick.

It is seen that the agreement between theory and measurement is not very good, especially for high (kl) values. The writer is not certain of the accuracy of these data and it is suspected that a considerable amount of the discrepancy is due to errors in measurement. These data are included mainly because they represent the most extensive check on the theory up to the present time.

The 60-cycle coil of Figure 2 was subsequently built and tested, and although tests were made only for (kl) values around 1.75, the agreement between theory and test was nearly perfect. Values of M (kl), R_1, R_2, and (X_1+X_2) were calculated from averaged measurements of coil voltage, coil current, and power input, with and without strip in the air-gap. These are listed in Table I and are labeled "Experimental." Corresponding values calculated from equations in the paper are shown for comparison and are labeled "theoretical." A field coil consists of ten turns of two 3/8-inch outside diameter copper tubes in parallel as shown in Figure 14. The dimensions of the slot are $2^1/_2$ inches wide by $5^1/_2$ inches deep and the air-gap is $2^3/_4$ inches. The iron is stacked to give a core width of 54 inches. Tests were made heating aluminum strip 54 inches wide by 0.04 inch thick traveling at a speed of approximately 30 feet per minute. Each pole structure carries six poles with a pole pitch of eight inches. The 12 field coils are connected two in series with six parallels. The terminal impedance is therefore one-third the impedance of a single field coil. The experimental installation is shown in Figure 15.

Table I

	Experimental	Theoretical
kl	1.74	1.74
M (kl)	0.34	0.36
R_1	0.041	0.044
R_2	0.009	0.005
(X_1+X_2)	0.159	0.159

The theoretical value of coil resistance R_1 is low because it was calculated simply from the cross-section and length of copper without considering eddy currents or skin effect. Also, iron loss was not included and iron loss automatically appears in the experimental value of R_2.

From these data it would appear that the equations derived in this paper are quite accurate. It also will be noted from the experimental values of R_1 and R_2 that an efficiency of better than 80 per cent can be expected. The fact that the equations developed in this paper have been used so successfully for designs at widely different frequencies such as 60 cycles and 10,000 cycles per second indicates that the theory is quite general.

Correction of Edge Heating—Magnetic Instability

As mentioned earlier in this paper, the movement of the strip through the air-gap tends to produce uniform heating everywhere except near the edges of the strip.

If the strip is narrower than the pole structures, the edges of the strip over-heat; and if the strip is much wider than the pole structures, the edges of the strip underheat. It was necessary to find a method for overcoming this difficulty which would be applicable to strips of different widths. A very satisfactory solution was found and is shown schematically in Figure 16. The pole structures are independently mounted on rollers so that their overlapping width can be made just enough less than the strip width to produce uniform heating across the strip. By looking closely at Figure 3, it will be noted that this pole structure was equipped with both vertical and horizontal rollers designed to run on suitable tracks. The pole structures also were equipped with independent photoelectric systems which automatically maintained a fixed distance between the edge of a pole structure and the edge of the strip.

Figure 16. Automatic aligning arrangement transverse flux coil—top view

This method proved satisfactory except for one very serious trouble. The current flow near and parallel to the edge of the strip (see Figure 4) tended to pull the edge of the strip down against the iron of the extended pole structure. This was an unexpected and surprising phenomenon when first observed because when heating a nonmagnetic strip like aluminum, the tendency near the center of the pole structure is and should be one of centering. The peculiar edge effect is explained by the attraction of a current-carrying conductor to a magnetic body near it. A satisfactory solution of this difficulty was obtained by attaching a U-shaped copper shield to the edge of each pole structure, as shown in Figure 17. The shield moves with a pole structure and shields the edge of the strip at all times from the attraction of the pole structure. The thickness of the material from which the shield is made should be equal to or greater than the depth of current penetration at the frequency of operation. To minimize losses, a low-resistivity material like copper should be used.

It is interesting to note that the system illustrated in Figures 16 and 17 not only automatically adjusts for strip width, but also will take care of weaving or sidewise motion of a strip.

Making a Design

Given a strip of specified dimensions and material to heat to a specified temperature at a specific linear speed, steps in making a design may be listed as:

1. Calculate the total power in watts required to heat the strip from purely thermal considerations, making suitable allowance for losses by radiation and convection.

2. Assume a length of pole structure (in direction of strip travel), and calculate the watts per cubic centimeter which must be generated in the strip.

3. Decide upon the air-gap necessary from mechanical considerations and, using the typical ratios of equation 38, arrive at suitable slot dimensions and pole pitch.

4. From equation 39 calculate the optimum frequency to use. If the calculated frequency is not readily obtainable, consider using a standard frequency near the calculated value and investigate the effect of the changed (kl) value by referring to the power-factor curves of Figure 12 and the power input function $M(kl)$ of Figure 9. It may be necessary to adjust the pole pitch to obtain a reasonable compromise.

5. From equation 36 calculate the value of magnetizing force H_0 required. Reasonable values of H_0 vary from 4,000 oersteds at 60 cycles to 1,000 oersteds at 10,000 cycles. If the value of H_0 falls outside this range, it may be necessary to lengthen the pole structures by adding more poles.

6. Using equations 22 and 29, proceed by a cut and try process to arrive at the number of turns in a field coil and the grouping of field coils to permit operation at the voltage of the chosen power source. It will usually be desirable to wind the coils from hollow copper tubing to permit water cooling.

7. Design the magnetic circuit, providing enough depth behind the slots to carry the total air-gap and slot-leakage flux without saturation and without undue iron loss. The thickness of laminations will be dictated by the frequency used. It may be necessary to provide ducts through the iron (across laminations) for forced air cooling.

8. Knowing the magnetizing force H_0 and the number of turns per coil, calculate coil current and copper loss. Knowing the flux density in various parts of the magnetic core and frequency, calculate iron loss. Knowing total loss and power input to the strip, calculate the expected conversion efficiency.

All of the derivations of this paper and the steps outlined above for making a design are carried out as if the strip was just as wide as the pole structures, and are furthermore based on the assumption that edge effects are corrected to produce uniform heating across the strip. Likewise, the curves of power factor, Figure 12, are valid only for this condition.

When the pole structures are shifted (as shown in Figure 15) to heat strip considerably narrower than the pole structures, the terminal power factor, the efficiency of conversion and the terminal impedance will all be reduced somewhat. Approximate corrections may be made, if desired, by using formulas in this paper.

Effect of Magnetic Permeability in Strip

It has been tacitly assumed throughout that the strip being heated is not ferromagnetic. Ferromagnetic strip like steel can be heated with transverse flux, although this is not generally recommended. The derived equations will be slightly in error for two reasons.

1. The presence of the ferromagnetic strip effects a slightly lower reluctance in airgap.

2. Some flux will be diverted through the strip from one pole to an adjacent pole on the same side of the strip. In so doing, a certain amount of longitudinal flux heating is produced. Using the optimum frequency for transverse flux heating calculated from equation 39, this effect is generally small because the strip saturates before much flux can be diverted, and the depth of current and flux penetration for longitudinal flux heating is large compared to strip thickness.

A Special Application of Transverse Flux Induction Heating

Whereas the aim thus far has been to produce uniform heating in a moving strip, there are some applications such as in the heating of skelp for making seam-welded steel pipe, where it is actually desirable to overheat the edges of a strip of metal.

Based on the foregoing analysis, it is obvious that such heating can be obtained by passing the strip between a pair of poles, as indicated in Figure 18. If the pole is long in the direction of strip travel compared to the width of the strip, the average power density may be calculated from equation 36. However, in determining (kl), one must take (l) as the width of the strip. The distribution of current density across the width of the strip will be a function of (kl) as shown in Figure 7. The power density distribution can be obtained for any (kl) value simply by plotting current-squared curves from those of Figure 7. If one wishes the major part of the heating to occur near the edges of the strip, the frequency must be chosen to make (kl) large.

Conclusions

1. Transverse flux induction heating provides a practical and efficient method for the continuous heat-treating of nonferromagnetic strip like aluminum, brass, copper, magnesium, or stainless steel.

2. Formulas derived in this paper allow one to design a transverse flux installation and predict performance with good accuracy.

3. Frequencies used will generally fall in the range between 60 and 10,000 cycles per second, and depend on the physical and electrical properties of the strip to be heated.

4. An efficiency of 80 per cent or better can be expected in most applications.

5. Special means can be provided to

accommodate various strip widths and insure uniform heating.

6. Transverse flux heating also is applicable to certain edge-heating applications.

No Discussion

Classification of the Reference Frames of a Synchronous Machine

GABRIEL KRON
MEMBER AIEE

THIS is the second part of a series of studies on the steady-state stability calculation of long-distance transmission systems as influenced by voltage regulators. The physical and hypothetical reference frames of a synchronous machine hitherto used or now contemplated are reviewed and classified from a dynamical and geometrical point of view. It is found that among the large number of possible reference frames, there exists one frame—representable by an equivalent circuit—possessing the remarkable properties that for any complex transmission system the sum of its i^2r losses is equal to the damping torques and the sum of the i^2x powers is equal to the synchronizing torques of the various generators. The significance of the tensorial formulation of the equations of hunting and the role played by the Riemann-Christoffel curvature tensor in the above physical picture is outlined.

The Limitations of Long-Distance Transmission of A-C Power

Present-day economics indicate the practicability of long-distance power transmission in many localities for distances greater than 300 miles. One of the important characteristics of an a-c transmission system is its steady-state stability limit. That is at some particular steady-state load and system condition, when the synchronous machine is still able to supply more power across the line, the system nevertheless loses synchronism. This is interpreted physically that the generator has no longer enough "synchronizing torque" to keep it in synchronism against small disturbances that continually arise.

It has been known that a voltage regulator attached to the field of the generator raises the steady-state stability limit to a higher value. The mechanism of this process has not been quite clear. No satisfactory physical theory of the small oscillations of a transmission system exists as yet and all attempts to explain physically the magnitudes of positive and negative damping and synchronizing torques of even such a simple system as a synchronous machine connected to an infinite bus, have led only to very complicated expressions without any clear-cut physical picture.

Purpose of the Paper

It is one of the purposes of this series of papers to develop a consistent and fairly simple physical theory of hunting of a transmission system that is correct dynamically and is useful as well in practice. Such a development requires a critical examination of the basic role played by the concept of "reference frame" in the physical pictures the engineer constructs to visualize the behavior of a rotating machine. Unlike conventional mechanical systems, an electrodynamical system offers different basic concepts and different physical pictures by a change of the relative velocities of the reference frames. While one reference frame gives the most satisfactory pictures for say sudden-short-circuit problems, another reference frame is needed to visualize in a simple manner the phenomenon of hunting. And the passage from one reference frame to another is not so simple a step as it is in a mechanical problem.

The purpose of the present paper is to point out the automatic appearance of new concepts and new physical entities as the relative angular velocities of the reference frames of a synchronous machine are varied, in order to lead up logically to the right reference frame to be employed in the study of hunting. In other words a search is instituted for a new type of reference frame in which, during hunting, some fluxes behave as springs (positive T_S), other fluxes behave as masses (negative T_S), and in which the resistances behave as frictions (positive and negative T_D). The actual study along the new reference frame will be undertaken in a subsequent paper.

Electrodynamics in Words of Many Syllables

Electrodynamics is a young and still very little developed or understood subject. Even such a simple topic as the electromagnetic field of free space viewed from a reference frame in uniform translation leads to 4-dimensional relativity with all its mystic connotations and formulae. Though in a synchronous machine the velocities are small compared to the speed of light, and though only magnetic fields, electric currents and rotating magnetic and conducting media appear, nevertheless the reference frames and the media have different relative angular velocities. This difference in rotational speed between conductors, magnetic materials and the observers themselves (the reference frames) leads to an electrodynamics that has no longer any parallel with conventional particle dynamics of moving material bodies. However the parallelism is still maintained with modern differential geometry whose development was instigated by this very need of electrodynamics for a unified treatment, though in fields other than electric machinery. Nevertheless any logical study of electric machinery must also necessarily lead to the same basic

Paper 50-114, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE North Eastern District Meeting, Providence, R. I., April 26-28, 1950. Manuscript submitted August 26, 1949; made available for printing February 27, 1950.

GABRIEL KRON is Consulting Engineer with the General Electric Company, Schenectady, N. Y.

Figure 1 (left). Six physical, rectangular reference frames of a synchronous machine

Figure 2 (right). Two points of view of a synchronous machine

concepts that appear in the electrodynamics of moving elementary particles, namely to multidimensional non-Riemannian spaces, to the "Riemann-Christoffel curvature tensor," to "nonholonomic" reference frames, and to similar euphonious polysyllabic expressions that modern geometry has invented for use in electrodynamics.

Whether the electrical power engineer likes it or not, he has no other choice. Only these strange-sounding creations of physicists and geometers fit the logic of the peculiar behavior of electric machines, and unfortunately even these creations are still very fragmentary and insufficient. Future progress in the theory of electrical power utilization lies clearly along these very channels and the engineer must necessarily stumble through these same pathways either blindfolded or with an intelligent understanding of their peculiarities and pitfalls. The engineer may and undoubtedly will eventually replace these words with something more pronounceable and practicable, but not the basic concepts the words stand for. These basic concepts and the equations they occur in, are among the very few concepts and equations that form the very foundations of modern physics.

The Reference Frames

It has been argued that there are only two industrially important a-c rotating machines, namely the synchronous machine and the induction machine; and for that reason it is not worthwhile to build up an elaborate theory for their analysis. The flaw in the argument is that there are not two, but only one type of a-c rotating machine. The transient equations of both structures are identical (if the role of the stator and rotor are interchanged) and the saliency, frequency, or speed are only incidental characteristics in the construction of a basic theory.

As a matter of fact the transient equations of all rotating electric machines are basically identical, be they direct or alternating current, synchronous or induction or commutator machines, and irrespective of whether their leads, brushes or slip rings are connected in shunt or series, in singly or in arbitrary combination. The difference between the various types of machines and even the difference between the various theories of any one particular machine, may be reduced to the statement that it is all a question of point of view, or technically speaking, it is all a question of the "reference frame" assumed.

The Primitive Synchronous Machine

That particular single machine, from which all other machines differ only by the reference frame assumed, will be called—for the present limited purpose—the "synchronous machine." (In other publications the author called it the "primitive" machine.) For purposes of simplicity a 2-phase machine will at first be considered, having a salient-pole rotor and smooth stator structure. The stator windings are identical along the two phases, those of the rotor differ. The existence of zero-sequence currents will be ignored for the time being.

Having settled that the electrical engineer needs to write down the transient equation of only one 2-phase machine consisting of one stationary and one rotating magnetic structure, each with two sets of windings at right angles to each other, Figure 1, his troubles are about to begin. Even forgetting the brushes, slip rings, the possible shunt and series connections and simply concentrating on isolated windings in each axis, numerous possibilities arise in deciding the elementary question whether the reference frames should be rigidly connected to the magnetic structure or should be free of them. (The conducting windings themselves are rigidly connected to their respective magnetic structures.) Four such different possibilities are enumerated in the order of their increasing physical complexity and the reasons for their selection discussed, see Table I.

The Holonomic Riemannian Reference Frame I

The most obvious assumption for the analysis of a synchronous machine is that the reference axes of all stator windings should be rigidly connected to the stator iron and copper and those of the rotor windings should be rigidly connected to the rotor iron and copper. In this frame the physics of the phenomenon is very simple and the transient voltage equation along each axis has the form

$$e = Ri + p\psi$$

This is the reference frame (although written for three phases instead of two) which is used by Park as a starting point in the development of his equations. This also is the reference frame along which books on physics and electrotechnics employ the "holonomic" form of the dynamical equations of Lagrange

$$f_\alpha = \frac{d}{dt}\left(\frac{\partial T}{\partial\left(\frac{dx^\alpha}{dt}\right)}\right) - \frac{\partial T}{\partial x^\alpha} + \frac{\partial F}{\left(\frac{dx^\alpha}{dt}\right)} \qquad (1)$$

accompanied by the statement that these equations represent the dynamical theory of "all" electric machines. This dynamical theory originally was developed by Maxwell almost a century ago and until recently no progress has been made by electrical engineers to extend it to commutator machines or to other reference

frames of a synchronous or induction machine.

In terms of tensors the voltage equations may assume two different forms, depending upon whether the variables are both i and ψ or i only. In particular

1. In terms of i only: $e = Ri + p(Li)$.
2. In terms of i and ψ: $e = Ri + p\psi$.

The torque equation is

$$f = \frac{1}{2}\frac{\partial}{\partial\theta}(i^* Li) = \frac{1}{2}\frac{\partial}{\partial\theta}(i^*\psi) \tag{2}$$

The resultant tensor equation, that includes both voltage and torque equations, is written as

$$e_\alpha = R_{\alpha\beta} i^\beta + L_{\alpha\beta}\frac{di^\beta}{dt} + [\beta\gamma,\alpha] i^\alpha i^\gamma \tag{3}$$

Here $[\beta\gamma,\alpha]$ is the "holonomic" form of the Christoffel symbol defined as

$$[\beta\gamma,\alpha] = \frac{1}{2}\left(\frac{\partial L_{\gamma\alpha}}{\partial x^\beta} + \frac{\partial L_{\alpha\beta}}{\partial x^\gamma} - \frac{\partial L_{\beta\gamma}}{\partial x^\alpha}\right) \tag{4}$$

where $L_{\alpha\beta}$ is the "metric tensor" representing all the self and mutual inductances and the rotor inertia. This tensorial equation can be derived from the dynamical equation of Lagrange[1] by simply replacing T by $L_{\alpha\beta} i^\alpha i^\beta/2$. Expressed in another way equation 4 is an "explicit," form of the Lagrangian equation itself. (Since it is assumed that the variables i^α are complex functions, the spin indices are shown in bold-face type instead of placing a bar over them.

Since the dynamical equation of Lagrange will soon prove helpless when other reference frames are to be introduced it is necessary to give a geometrical interpretation to the above two dynamical equations. Geometrically the equations represent the motion of a point particle in an n-dimensional Riemannian space expressed along a holonomic reference frame. The geometrical language will rescue dynamics from an apparent breakdown.

The Nonholonomic, Riemannian Frame II(a)

Of course electrical engineers are aware that the previous equations can be used only in exceptional cases because of the analytical complexity introduced by the cos θ, sin θ terms in the metric tensor L Blondel and later on Park introduced a new, more practical set of equations in which these trigonometric functions no longer occur, by assuming that both stator and rotor reference frames are rigidly connected to the rotor only. This theory now is called the "2-reaction theory."

From the point of view of this paper it is very important to note that now the equations do not have the same form as in the previous frame but contain an additional speed term $p\theta_r$ as

$$e = ri + p\psi_d - \psi_q p\theta_r$$

Also the torque assumes a different form

$$f = i^q\psi_q - i^q\psi_d$$

The appearance of an additional speed term is due to the fact that the new stator reference frame, no longer connected to the stator magnetic structure, is a so-called "nonholonomic" reference frame to which the usual "holonomic" equations 1 to 3 no longer apply. This fact was recognized by the author in reference 3 showing that the Park-Blondel equations correspond exactly to the "nonholonomic" form of the dynamical equations of Lagrange given in many advanced books on dynamics

$$f_\alpha = \frac{d}{dt}\left(\frac{\partial T}{\partial\left(\frac{dx^\alpha}{dt}\right)}\right) - \frac{\partial T}{\partial x^\alpha} + \frac{\partial F}{\partial\left(\frac{dx^\alpha}{dt}\right)} + \frac{\partial T}{\partial\left(\frac{dx^\alpha}{dt}\right)} \times \left(\frac{\partial C_k^{\ b}}{\partial x^n} - \frac{\partial C_n^{\ b}}{\partial x^k}\right) C_\alpha^{\ k} C_\beta^{\ n}\left(\frac{dx^\beta}{dt}\right) \tag{5}$$

The transformation tensor $C_\alpha^{\ \alpha'}$ always appears in such equations and relates the nonholonomic frame to the holonomic one. The term containing it, namely

$$\Omega_{\alpha\beta}^{\ \ b} = \left(\frac{\partial C_k^{\ b}}{\partial x^n} - \frac{\partial C_n^{\ b}}{\partial x^k}\right) C_\alpha^{\ k} C_\beta^{\ n} \tag{6}$$

is the so-called "nonholonomic object," a nontensor geometric object, that will play an important part later on.

In terms of tensors the voltage and torque equations are (if γ is the "coefficient of rotation" containing only ± 1)

In terms of i only: $e = Ri + Lpi + \gamma Lp\theta_r i$

In terms of i and ψ: $e = Ri + p\psi + \gamma\psi p\theta_r$

$$f = i^* \gamma Li = i^* \gamma\psi \tag{7}$$

In these equations γ is not a tensor. The resultant tensorial equation is

$$e_\alpha = R_{\alpha\beta} i^\beta + L_{\alpha\beta}\frac{di^\beta}{dt} + [\beta\gamma,\alpha] i^\beta i^\gamma \tag{8}$$

where $[\beta\gamma,\alpha]$ is now the "nonholonomic" form of the Christoffel symbol, containing the nonholonomic object $\Omega_{\beta\gamma,\alpha}$ of equation 6 also in its definition. Geometrically both the Lagrangian and tensorial equations 5 and 8 may still be pictured as the motion of a point in an n-dimensional Riemannian space which however now is rigged up at every point by a nonholonomic reference frame, instead of a holonomic one.

For an induction motor the same equations apply except that often the role of stator and rotor are interchanged.

The Holonomic, Non-Riemannian Frame II(b)

It was shown in reference 3 that because of the "cylindrical" properties of the variables (for instance the relations between the currents, namely $C_\alpha^{\ \alpha'}$, are functions only of θ) there is nothing in the new equations to indicate that they were derived from some holonomic frame. For that reason it is possible to consider them on their own strength as basically new equations having their own special physical interpretation. Such a reformulation is accomplished by considering the expression in equation 6 defining the nonholonomic object $\Omega_{\alpha\beta,\gamma}$, not a nontensor object, but a tensor, the so-called "torsion tensor" $S_{\beta\gamma\alpha}$. In consequence γ in equation 7, the voltage, also becomes a tensor, the "rotation tensor."

Although this reformulation becomes mathematically useful only in going over to a new reference frame (as $S_{\beta\gamma\alpha}$ has a different law of transformation from that of $\Omega_{\beta\gamma,\alpha}$) it becomes physically important even in this particular reference frame. Since ψ is always a tensor and γ becomes now a tensor (because of the redefinition) their product $\gamma\psi$ must necessarily also be a tensor, a new physical entity, the so-called "flux-density" B of the armature. This is the same physical concept B that occurs in Maxwell's field-equations. (The flux-linkage ψ that occurred hitherto corresponds to the vector-potential A of Maxwell.) The new tensorial voltage and torque equations become

In terms of i only: $e = Ri + Lpi + Gip\theta_r$

In terms of i and ψ: $e = Ri + p\psi + \gamma\psi p\theta_r$

Table I. Rectangular Reference Frames of a Synchronous Machine

Attachment of Stator and Rotor Reference Frames	Actual Machine Physical	Actual Machine Hypothetical	Equivalent Circuit Physical	Equivalent Circuit Hypothetical
I.....One fixed to rotor, one to stator.....	1	7	13	19
II.....Both fixed to rotor.....	2	8	14	20
Both fixed to stator.....	3	9	15	21
III.....One fixed to rotor, one free.....	4	10	16	22
One fixed to stator, one free.....	5	11	17	23
IV.....Both free.....	6	12	18	24

In terms of i, ψ, and B: $e = Ri + p\psi + Bp\theta_r$

$$f = i^* Gi = i^* \gamma\psi = i^* B \quad (9)$$

In these equations of is a tensor. This physical reinterpretation has several advantages, among others:

1. It enables to assume that the new equations also are valid for commutator machines. In such machines it is an absolute necessity to introduce both physical concepts ψ and B, as there exist no simple relations between "flux-linkage" ψ and "flux-density" B, and they must be and are considered independent of each other. (That is in commutator machines B is no longer expressible as $\gamma\psi$.)

2. The torque can now be expressed as a generalization of the force equation of Maxwell, namely of $f = iB$.

3. The concept of B enables the construction of equivalent circuits on a more logical basis. In assuming symmetrical components, it is possible to measure on the equivalent circuit the components of B as differences of potential. (In assuming the physical axes d and q, the equivalent circuits allow to measure ψ but not B.)

4. During small oscillations an additional new physical entity, a flux-linkage, may be derived from B (as γB) corresponding to the much sought after "spring" that keeps the machine in synchronism.

A further advantage of the reinterpretation is shown later on.

It is emphasized that all three forms of the equations (containing i only, or i and ψ or i, ψ and B) are equivalent mathematically and their choice depends on convenience only. One form may be sometimes shorter, the other may give a more visual physical picture. For instance if the field axes of a synchronous machine are permanently eliminated by the use of operational impedances then the use of i and ψ requires the least number of symbols.

Unfortunately conventional rigid dynamics has no equations—analogous to the Lagrangian forms, equations 1 and 5, —that could represent this new dynamical system containing B or, for that matter, that could represent a d-c machine with commutators. Geometry now comes to the rescue. The resultant tensorial equation (including both voltage and torque equations), can be written in the form of a shortest line between two points

$$e_\alpha = R_{\alpha\beta} i^\beta + L_{\alpha\beta} \frac{di^\beta}{dt} + \Gamma_{\beta\gamma,\alpha} i^\beta i^\gamma \quad (10)$$

This equation also is sometimes called the generalized Lagrangian equation as it is derivable from a variational principle. Here $\Gamma_{\beta\gamma,\alpha}$ is called the "affine connection" and contains besides the holonomic Christoffel symbol $[\beta\gamma,\alpha]$ also the torsion tensor $S_{\beta\gamma\alpha}$ in its definition. (If time harmonics also are considered, $[\beta\gamma,\alpha]$ is not zero in a synchronous machine.)

Geometrically the new equation represents the motion of a point in a non-Riemannian space rigged up with a holonomic frame (instead of a Riemannian space with nonholonomic frames). That the frame still may be considered as holonomic, is seen from the fact that all the reference axes are still connected rigidly to one of the magnetic structures. The appearance of the non-Riemannian space (a space with "torsion") is due to the motion of the conductors with respect to the reference axes. That is even though the observer sees the current-density wave stationary, the conductors themselves replace one another in succession. (The "metallic metabolism" of Hoffman, reference 5.)

The "Electromagnetic-Field Tensor"

The appearance of a new physical entity due to the reinterpretation is shown more emphatically by the introduction in the last tensor equation of a skew-symmetric "electromagnetic-field" tensor $F_{\alpha\beta}$ containing B (for the voltage) and $-B$ (for the torque). In terms of this important tensor the equation of motion of a synchronous machine, equation 10 becomes

$$e_\alpha = R_{\alpha\beta} i^\beta + L_{\alpha\beta} \frac{di^\beta}{dt} + [\beta\gamma,\alpha] i^\beta i^\gamma + F_{\alpha\beta} i^\beta \quad (11)$$

where $[\beta\gamma,\alpha]$ is the holonomic Christoffel symbol. This equation is exactly the same as equation 3 except for the presence of the added term $F_{\alpha\beta} i^\beta$. Hence a physical entity is made to appear or disappear at will by a mere change in the reference frames.

If e_α and $R_{\alpha\beta}$ are made equal to zero this last equation also represents the classical or relativistic motion of a charged particle in an electromagnetic field. This tensorial equation of motion also plays a basic role in the theories of elementary particles of nuclear physics.

Summarized, from the new point of view the equations of a synchronous generator or induction motor become identical in form with those of a commutator machine, either alternating or direct current.

A more detailed discussion of the foregoing reinterpretation is given in reference 5.

The Nonholonomic, Non-Riemannian Frame III

While the physical concepts i, ψ and B appear to be sufficient for steady-state and sudden short-circuit (constant speed) problems, they prove to be unsatisfactory for acceleration problems, in particular for small oscillation (hunting) problems. That is when all reference frames are rigidly connected to the rotor, the frames also oscillate when the rotor does and at least two disadvantages follow:

1. If a transmission line is connected to the stator of the synchronous machine, the oscillatory stator reference axes introduced extra generators into each mesh of the line.

2. Even if no line is connected to it, no clear-cut physical picture can be developed for the damping and synchronizing torques of a synchronous machine, as the many unsuccessful trials indicate. There is something missing from the theory.

Both of these difficulties are removed if the stator reference-frame is divorced from the rotor and is allowed to rotate uniformly. Separating the stator reference frame from the rotor magnetic structure is again equivalent to the introduction of a nonholonomic reference frame. In analogy to equation 7 an additional speed term $p\theta_f$ appears (in addition to the rotor speed $p\theta_r$), so that a representative circuit equation has the form

$$e = Ri + p\psi + Bp\theta_r + \varphi(p\theta_f - p\theta_r)$$

where φ is a new type of flux density produced by the currents passing through the nonoscillating stator reference frame. The rotor reference frame still oscillates with the rotor structure.

The tensorial voltage equation now assumes four different forms

$$\begin{aligned} e &= Ri + Lpi + Gipe_r + Vi(p\theta_f - p\theta_r) \\ e &= Ri + p\psi + \gamma_1\psi p\theta_r + \gamma_2\psi(p\theta_f - p\theta_r) \\ e &= Ri + p\psi + Bp\theta_r + \gamma_2\psi(p\theta_f - p\theta_r) \\ e &= Ri + p\psi + Bp\theta_r + \varphi(p\theta_f - p\theta_r) \end{aligned} \quad (12)$$

It so happens that in a synchronous machine the second form simplifies to

$$e = Ri + (p + \gamma_2 p\theta_f)\psi = Ri + p\psi$$

since γ_1 (a tensor) is equal numerically to γ_2 (a nontensor). The cancellation of two equal terms having opposite signs is not allowable from a tensorial (physical) point of view and it would lead to a non-visualizable hunting equation unless B and φ are reintroduced somehow during the manipulations. Due to the simplicity of its derivation this last form will be used in the development of the equivalent circuit of hunting of a synchronous machine.

When the rotor velocity $p\theta_r$ is zero, then the new moving reference frame is identical with that used in the first part of this series of studies in connection with stationary networks (reference 1). If in the above four equations $p\theta_r$ is made equal to zero, the equations derived here are reduced to the simplicity of those given in reference 1 for a stationary network with no capacitors.

Along the new, uniformly rotating reference frame the torque equation remains unchanged while the resultant tensorial equation, representing also the generalized Lagrangian equation assumes the form

$$e_\alpha = R_{\alpha\beta} i^\beta + L_{\alpha\beta} \frac{di^\beta}{dt} + \Gamma_{\beta\gamma,\alpha} i^\beta i^\gamma \qquad (14)$$

where the affine connection $\Gamma_{\beta\gamma,\alpha}$ contains now the nonholonomic form of $[\beta,\gamma,\alpha]$, hence the nonholonomic object $\Omega_{\beta\gamma,\alpha}$, in addition to the torsion tensor $S_{\beta\gamma\alpha}$. Geometrically the equations describe the motion of a point in a non-Riemannian space rigged up with a nonholonomic reference frame.

It is emphasized that it is not at all an absolute necessity to introduce four physical concepts i, ψ, $\boldsymbol{B}$ and φ even in this particular reference frame. Also it is possible to consider the uniformly rotating frame still as a nonholonomic, Riemannian frame containing only two physical concepts i and ψ, by starting with frame number 1 and immediately passing to frame number 4, giving an equation of voltage analogous to equation 7

$$e = Ri + p\psi + \gamma\psi p\theta_r \qquad (15)$$

Here γ is a nontensor geometric object. However by leaving out frame number 2 as an intermediary step the simplified physical picture of hunting disappears.

A Better Physical Picture

A more visual physical picture of the three physical concepts may be given by assuming the field stationary and the armature rotating with $p\theta_r$ (Figure 2). Then frame number II is represented by stationary brushes and frame number III is given by assuming the brushes to oscillate around their stationary position in unison with the rotor oscillation with $p\theta_f - p\theta_r$. Then:

1. ψ is the flux-linkage of all windings, that induces voltages while the rotor and the reference frames all are stationary and the currents vary in time.

2. $\boldsymbol{B}$ is the flux-density of the armature windings that is cut by the rotor velocity $p\theta_r$, assuming the frames stationary and the currents constant. It lies at right angles in space from ψ_r of the armature.

3. φ is the flux-density that oscillates with the brush velocity $p\theta_f - p\theta_r$ and cuts both stator and rotor conductors, assuming the rotor stationary and the currents constant. This flux-density is produced only by the currents passing through the oscillating brushes.

Additional Flux Concepts and the Synchronizing Torques

If this last physical reference frame is used with its three flux concepts ψ, $\boldsymbol{B}$, and φ, then during hunting two additional flux-concepts appear that separate the resultant synchronizing torque into positive and negative components. The two additional fluxes are:

1. $\boldsymbol{B}\dagger$ is a flux-linkage at right angles in space to $\boldsymbol{B}$, hence numerically equal to the negative of the armature flux-linkage ψ_r

$$B\dagger = -\gamma B = -\gamma Gi = Ki = \psi_r \qquad (16)$$

This is a flux that acts as a spring to bring the rotor back to its original position when displaced by $\Delta\theta_r$. This flux is responsible for the existence of a permanent synchronizing torque in the absence of a voltage regulator or even in the

Figure 3. The two types of hunting networks of a transmission system

absence of hunting-frequency currents. The coefficient of i, namely K, is the "curvature-tensor." The tensor of valence four $K_{\alpha\beta\gamma\delta}$ built up from K (for the voltage) and $-K$ (for the torque) is the "Riemann-Christoffel curvature tensor."

The statement that the curvature tensor is an approximate measure of the steady-state stability of a synchronous machine is analogous to a similar generalization made by engineers about the short-circuit ratio.

2. $\varphi^{\dagger}$ is a flux-linkage at right angles in space to φ

$$\varphi^{\dagger} = \gamma\varphi = \gamma V i = G\Gamma i \tag{17}$$

This is a flux that acts as an apparent increase in the rotor moment of inertia, responsible for the appearance of a negative synchronizing-torque component during hunting.

When engineers talk about improving steady-state or transient stability by reducing the "transient reactance," or redesigning the voltage regulator, their statements are equivalent to expressing the coefficient of i, namely $G\Gamma$, in simple practical terms. (Not being a tensor, the latter has no single symbol or distinctive name.)

Additional Current Concepts and the Damping Torques

It is interesting that none of these flux concepts has any bearing upon the positive and negative damping torque components. The latter depend upon new current concepts that however appear only during small oscillations and then only along the last reference frame number III.

In the first two reference frames, Figure 3(A) the current concept i introduces during hunting the sole concept δi. But in frame number III, Figure 3(B) three new currents appear during hunting. In particular:

1. In the synchronous machine flows δi. It is a tensor, the so-called "absolute change" in i.

2. In the machine resistances and in the transmission line flows Δi (not a tensor).

3. Their difference $\Gamma i \Delta\theta_r$ (not a tensor) flows in a shunt between the machine and the line (when represented by an equivalent circuit)

$$\delta i = \Delta i - \Gamma i \Delta\theta_r \tag{18}$$

In the presence of this tensorially correct redistribution of currents all resistances act as positive or negative frictions tending to damp out or enlarge any small oscillations that arise.

A Still More General Frame IV

In analyzing the small oscillations of a polyphase induction motor, the conventional reference frame number III stationary with respect to the stator (the "cross-field" theory) introduces sinusoidal steady-state currents of fundamental frequency f along each axis. During hunting two sets of equations must be written, however, one set having $f+h$ frequencies, the other set $f-h$ frequencies. If now a uniformly rotating frame is assumed on both stator and rotor that rotates with the steady-state field and does not take part in the oscillations, then:

1. All steady-state currents are direct current (zero frequency).

2. Only one set of h frequency currents appears.

The analysis of hunting becomes thereby parallel to that of a synchronous machine (see reference 2, page 118). Dynamically and geometrically their theory may be assumed to be the same as those of frame number III. Or at least no need arose as yet to investigate whether additional physical concepts might be desirable in frame number IV.

The 24 Basic Reference Frames

In connection with each of the foregoing four types of physical reference frames (extended to six by interchanging the roles of stator and rotor) it is possible to introduce hypothetical "symmetrical component" frames (positive- and negative-sequence frames) provided the real variables i are replaced by complex variables even in the transient equations. These additional six frames are shown in the second column of Table I. Several of these were already used on previous occasions leading to simpler equations and more visual physical pictures.

In connection with each physical and each hypothetical frame it is possible to introduce still another reference frame that allows the equations to be represented by a stationary electrical network. This possibility doubles the number of frames of a synchronous machine, as shown in Table I, columns 3 and 4.

The Remarkable Properties of Reference Frame Number 22

While the physical frame number 4 (belonging to group III) separates the fluxes into equivalent springs and masses, and the resistances into positive and negative frictions, nevertheless the actual *magnitudes* of the various damping and synchronizing torques still are not clearly brought out in that frame. However there exists among the four reference frames of group number III one set that correctly gives the magnitudes of the individual torque components also. That particular frame is number 22 which also allows the representation of the synchronous machine and its connected power system in the form of a stationary network along the forward and backward (f and b) sequence axes.

Considering any large transmission system consisting of several synchronous machines, voltage regulators, transmission lines and other connected apparatus, —all expressed along reference frame number 22—the following relations exist between the power flow in the transmission system and the machine torques.

1. The damping torque T_D of each machine is the sum of the i^2r losses in the various portions of the system.

2. Similarly the synchronizing torque T_S of each machine is the sum of the i^2x powers stored in the various portions of the system.

It is interesting and important to note that none of the other reference frames of groups number I to number III mentioned hitherto is capable of this elegant physical interpretation. In the Blondel-Park frame number II, even though it is expressed in the form of an equivalent circuit along frame number 20 (Figure 3(A), the i^2r losses have nothing whatever to do with the damping torques, nor have the i^2x powers any connection with the synchronizing torques. By inference from Figure 3(B), however, some isolated relations may be established for 3(A) also.

Moreover it cannot be sufficiently emphasized that it is not adequate merely to express the equations of the synchronous machine along frame number 22. The equations must be developed in a strictly tensorial form involving the Riemann-Christoffel curvature tensor. It is possible to express the equations of frame number 22 in a conventional manner and develop even an equivalent circuit for it. But there exist no simple relations between torques and powers and the equivalent circuit is devoid of such simple physical meanings.

The physics of small oscillation of rotating electric machines, or of any dynamical system for that matter, is intimately connected with the curvature tensor. Without it the physics of the phenomenon must be expressed in terms of artificial, nontensorial concepts that do not lend themselves to easy visualization.

The derivation of this interesting equivalent circuit of a synchronous machine, Figure 3(B), representing reference frame number 22 in a tensorial formulation, will be the subject matter of a subsequent paper.

Doubling the Number of Reference Frames

To each of the 2-phase axis of a winding belongs a third, the zero-sequence axis, that hitherto has been ignored since it does not take part in the transformations. However on both stator and rotor of each of the 24 types of reference frames it is possible to assume three axes at 120 degrees from each other, representing a 3-phase winding. Even though the analysis itself is usually performed in terms of 2-phase axes, in many cases the final results must be reinterpreted in terms of the actual 3-phase winding.

Practically all problems can be and should be analyzed first in terms of the simpler 2-phase (and zero sequence) frame to save labor, and then only should the results be transformed to the actual 3-phase frame. Similarly since all transformations are easier to perform from a 2-phase to another 2-phase frame, consequently 3-phase transformations should be avoided if at all possible. However these precautions were not followed by Park in his basic work, who performs his transformation from frame number 1, considered as 3-phase axes, to frame number 2 considered as 2-phase axes. The apparent difficulty of his work is partly due to his going from the $\boldsymbol{a}$, $\boldsymbol{b}$, $\boldsymbol{c}$ to the $\boldsymbol{d}$, $\boldsymbol{q}$, $\boldsymbol{o}$ axes without first changing to the 2-phase axes $\boldsymbol{\alpha}$, $\boldsymbol{\beta}$, $\boldsymbol{o}$ on the same holonomic physical frame. (The author in his book[1] performs all transformations always from $\boldsymbol{\alpha}$, $\boldsymbol{\beta}$ to $\boldsymbol{d}$, $\boldsymbol{q}$ or vice versa. He denotes $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ by $\boldsymbol{a}$ and $\boldsymbol{b}$.)

Some More Reference Frames

When a reference frame is not connected rigidly to the structure but is free to move, several possibilities may arise. The reference frame may be accelerated or may have an arbitrary uniform velocity. It may follow the motion of some other structure or of the rotating flux. Also the stator reference frame may rotate with speeds different from those of the rotor frame.

The number of possible reference frames increases greatly if the angle between the axes changes from 90, or 120, degrees. (A shaded-pole induction motor is an example.) If the various axes of the stator and rotor also are interconnected in shunt or series (as in a-c and d-c commutator machines) the possible number of frames grows by leaps and bounds. When several machines and stationary networks are interconnected and when other than electrodynamical systems also are interlinked into one unit, the number of possible reference frames becomes inexhaustible. It cannot be sufficiently emphasized that it is possible to establish equations for any one reference frame by starting with those of any other frame. From a mathematical point of view all reference frames are of equal value (all form one "group") though the use of any one particular frame is dictated by some practical necessity.

The Evolutionary Growth of Electrodynamic Concepts

One other characteristic of electrodynamical systems must be pointed out. Because of the cylindrical properties of the variables it was possible to introduce two sets of physical concepts along frame number II. In going over to a new reference frame number III, either of the two sets of physical entities may be carried along. Moreover since it is possible to arrive to frame number III from frame number I without the intermediary step of frame number II, it is possible to attribute to frame number III at least three different sets of physical entities, each associated with a different type of physical picture. The situation is complicated by the fact that in returning from frame number III to frame number II the original set of equations and physical entities need not necessarily be re-established.

It has to be recognized that in electrodynamics it is not sufficient merely to state what reference frame is being used. It also is necessary to define all the intermediary reference frames, the physical interpretation (type of geometrical space) attributed to the intermediary frames, also the original starting frame and equations that have been employed in arriving to the working equations.

In other words, a characteristic of electrodynamics is that the history of the succession of reference frames and geometrical spaces employed leaves its imprint upon the nature of the physical entities that happen to exist along any particular type of reference frame.

The Elementary Books on Tensor Analysis

It is rather unfortunate that most introductory books on tensor analysis only cover the study of 3-dimensional holonomic Euclidean and Riemannian spaces, all of which are practically useless to represent the physical concepts dealt with by the electrical power engineer. What is worse, even in these restricted spaces the authors assume only real transformations (in electric machinery during steady state and during hunting the currents are complex, not real). In addition usually all transformations occur only between equal number of variables (nonsingular transformations) while in interconnecting electric machines and networks most transformations are singular (the interconnected system has fewer number of variables). Needless to say that all such books are also full of geometrical theorems that are of no earthly use to the power engineer.

It is emphasized though that such restricted analysis of a holonomic Riemannian space with real variables and nonsingular transformations is still valuable to the engineer who is interested in conventional 2- and 3-dimensional field problems such as heat-flow, fluid dynamics, electromagnetic fields, et cetera. For him tensor analysis represents, however, only an improved presentation of the concepts of conventional vector analysis. But outside of serving as a short introduction to the more advanced concepts of tensor analysis the electrical power engineer, interested in circuits and machines as opposed to fields, will find a more than cursory study of elementary books on tensors disappointing and a waste of time.

The Advanced Concepts of Tensor Analysis

Although each winding of a rotating electric machine is a 2-dimensional field and an entire machine is a collection of such interconnected 2-dimensional fields, the spaces described by the currents in the windings are not holonomic and Riemannian, but nonholonomic and non-Riemannian, as demonstrated previously. Moreover a transmission system is not merely an n-dimensional space, it is rather a conglomeration of interconnected and interlinked zero-, 1- and 2-dimensional Euclidean, Riemannian, and non-Riemannian spaces, all rotating, sliding and intertwining with each other. The concept of "interconnection of spaces" transgresses the boundaries of "differential geometry" and encroaches upon the territory of "topology."

The writer knows of only two books[6,7] that cover the geometry of the general spaces and the type of transformations

that arise in electrical power engineering. (The geometrical analogues of resistances, capacitances and impressed forces are still absent in these books, so is the concept of interconnection of different types of spaces.) Curiously enough, one of their authors, Schouten, the creator of several of these spaces, was himself originally an electrical engineer specializing in rotating electric machinery. (Several of his engineering contributions are to be found in the Elektrotechnische Zeitschrift.) In his search for a co-ordinating engineering tool more general than vector analysis, he became interested in tensor analysis and never again did he turn back to vector analysis or to engineering. Schouten has been applying these non-Riemannian spaces during the last three decades to the study of the atomic nucleus and its elementary particles in place of electric machinery.

The electrical engineer will be surprised to find how the very same tensorial concepts mentioned in these pages turn up over again in the study of the motion of the elementary particles of nuclear physics or of the stars of distant nebulae (cosmology) as a glance through any issue of the Physical Review would show. These fascinating analogies are additional driving forces behind the authors insistence upon the rigorous tensorial formulation of each new physical entity he is called upon to employ. These analogies from the world of atoms and of stars serve as inexhaustible sources of information and inspiration for the further extension of knowledge concerning the behavior of such man-made creations as electrical power networks and power machinery.

No Discussion

The Calculation of the Capacitance of Coaxial Cylinders of Rectangular Cross-Section

GEORGE M. ANDERSON
ASSOCIATE AIEE

IN A recent paper, T. J. Higgins and R. D. Teasdale,[1] using experimental techniques, have made a thorough study of the capacitance per-unit length of copper bus-bars set in concrete cells.

A cross-section of a typical arrangement is shown in Figure 1. The cylindrical conductor of rectangular cross-section, at line potential, is arranged symmetrically within a concrete cell assumed to be at zero potential. Results of the investigation show graphically the variation of capacitance per centimeter with side lengths. An empirical relation also is given for the case of square cross-sections.

The purpose of the present paper is to develop analytical formulas and methods for calculating the capacitance per-unit length of configurations of this type. The field problem is assumed to be two dimensional; that is, it does not depend on the long dimension of the cylinders. The cylinders themselves are assumed to be equipotentials and their orientation with respect to each other is as shown in Figure 1.

Two approaches are presented: (1) an exact solution based on the work of Bergman,[2,3] which permits the calculation of capacitance from a simple formula for a square coaxial cylinder or for the rectangular case provided the side lengths in the latter case satisfy a given restraining condition, and (2) an approximate calculation for those cases where the exact solution does not apply.

Part III, the section on Comparison of Calculated and Experimentally-Determined Values of Capacitance compares, in a few instances, calculated values of capacitance with the experimentally-determined values of Higgins and Teasdale. Their experimentally-determined values appear to have an error of from 4 to 8 per cent, always high.

I. An Exact Solution

The calculation of the capacitance of configurations in which the field is two dimensional can often be effected with the aid of conformal transformations of a complex variable. A suitable transformation transforms the given problem into a new problem for which the solution is known or can be found. When the boundary of the configuration is a closed polygon of straight sides, the Schwarz-Christoffel integral offers a systematic approach to finding the desired transformation.

Bergman,[2,3] using this method, has investigated the magnetic field in a single-phase transformer. With the aid of certain simplifying assumptions, he reduced the transformer problem to that of the "L" of Figure 2(A), in which AF and CD are magnetic equipotentials and ABC and DEF are lines of magnetic flux.

From symmetry considerations it is apparent that the capacitance problem of the rectangular cylinders may be reduced to determining the capacitance of the "L" of Figure 2(A), in which AF and CD now are taken as lines of electric flux and ABC and DEF are electric equipotentials. The capacitance of the cylinders is then four times the capacitance of the "L." Bergman's work may therefore be applied directly.

The details of the analysis are contained in the Appendix.

The results of the analysis, which apply only when equation 4 is fulfilled, show that the capacitance of the rectangular cylinders of Figure 1 may be computed from*

$$C = 2\varepsilon_0 \frac{K(x')}{K(x)} \tag{1}$$

where $K(x)$ and $K(x')$ are complete elliptic integrals of the first kind[4,5,6,7] to the moduli x and x' respectively. (The prime notation is used to designate the complimentary modulus. Thus $x'^2 = 1 - x^2$.)

The modulus x is given by

$$x^2 = \frac{k_2^2}{k_1^2} \frac{(1-k_1^2)}{(1-k_2^2)} \tag{2}$$

where k_1 and k_2 are also moduli of complete elliptic integrals of the first kind determined in terms of the side lengths of one of the four "L's" of the rectangular cylinders by

$$\frac{K(k_1)}{K(k_1')} = 2\left[\frac{(AB)-(CD/2)}{(AF)}\right];$$
$$\frac{K(k_2)}{K(k_2')} = \frac{1}{2}\left[\frac{DC}{(BC)-(AF)/2}\right] \tag{3}$$

The condition of restraint mentioned above requires that k_1, k_2, and the side lengths satisfy

$$\frac{K(k_2)}{K(k_1')} = \frac{(DC)}{(AF)} \tag{4}$$

This condition is always satisfied when there is symmetry, that is when $(AB) = (BC)$ and $(DE) = (EF)$. (In this case $k_1^2 + k_1'^2 = 1$.) If equation 4 is not satisfied this method is not applicable.

Paper 50-115, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE North Eastern District Meeting, Providence, R. I., April 26–28, 1950. Manuscript submitted November 15, 1949; made available for printing February 27, 1950.

GEORGE M. ANDERSON is with the Carnegie Institute of Technology, Pittsburgh, Pa.

The author wishes to express his thanks to Professor B. R. Teare for his encouragement during the course of this work and for his helpful comments and suggestions in the preparation of the paper. Thanks also are extended to Professor A. Heins for a useful discussion of the problem and to Professor G. Handelman for reference 3.

*The dielectric is taken to be air. Meter-kilogram-second rationalized units are used throughout this paper. In this system $\varepsilon_0 = (10^{-9})/36\pi$.

Approximations to the Elliptic Integrals

For extreme values of the modulus, x, in equation 1, it is desirable to use approximations to $K(x)$ and $K(x')$. A particularly suitable approximation, since it deals directly with the ratio of $K(x)$ to $K(x')$, is given by Whittaker and Watson.[8]

If $k^2<0.5$, then

$$\frac{K(k')}{K(k)}=\frac{1}{\pi}\log_e(1/q) \tag{5}$$

where

$$q=\varepsilon+2\varepsilon^4+15\varepsilon^9+150\varepsilon^{16}+\ldots$$

and

$$2\varepsilon=(1-\sqrt{k'})/(1+\sqrt{k'})$$

ε has a maximum value

$$\varepsilon_{max}=0.087$$

so that

$$q\approx\varepsilon$$

with an error of less than eight parts per million, and

$$\frac{K(k')}{K(k)}\approx\frac{1}{\pi}\log_e 2(1+\sqrt{k'})/(1-\sqrt{k'}) \tag{6}$$

If $k^2>0.5$, it is similarly established that

$$\frac{K(k)}{K(k')}\approx\frac{1}{\pi}\log_e 2(1+\sqrt{k})/(1-\sqrt{k}) \tag{7}$$

Approximations to the Moduli of the Elliptic Integrals

Equations 6 and 7 can, of course, be inverted to find the modulus when the ratio of the integrals is known as required in equation 3. The advantage, of course, being that the cut and try process necessary with the elliptic integral tables is eliminated and the result is expressed in terms of the more elementary functions.

Let

$$\frac{K(k)}{K(k')}=y$$

If $y<1$, then from equation 6

$$k'=\sqrt{1-k^2}\approx\left[\frac{1-2e^{-\pi/y}}{1+2e^{-\pi/y}}\right]^2=\tanh^2\left[\frac{(\pi/y)-\log_e 2}{2}\right] \tag{8}$$

and if $y>1$, from equation 7

$$k\approx\left[\frac{1-2e^{-\pi y}}{1+2e^{-\pi y}}\right]^2=\tanh^2\left[\frac{\pi y-\log_e 2}{2}\right] \tag{9}$$

Example

To illustrate the numerical calculations consider the case of a square coaxial cylinder with dimensions

$$\frac{(AB)}{(EF)}=3.0;\quad (AB)=(BC);\quad (DE)=(EF)$$

Figure 1. Cross section of rectangular cylindrical capacitor

From equation 3

$$\frac{K(k_1)}{K(k_1')}=\frac{K(k_2')}{K(k_2)}=\frac{[(AB)/(EF)]+1}{[(AB)/(EF)]-1}=2.0$$

K. Hayashi[7] gives a table of $K(k)/K(k')$ from which k_1 and k_2 may be determined directly.

If this table is not available, k_1 and k_2 can be found after some experimentation using the tables for $K(k)$.

Let

$$k_1=k_2'=\sin\theta$$

then

$$k_1'=k_2=\cos\theta$$

and from the tables

$$\theta=80 \text{ degrees } 6 \text{ minutes}$$

From equation 2

$$x^2=(k_1/k_1')^4=\cot^4\theta=0.03046$$

Using the elliptic integral tables directly we find

$$K(x)=1.571;\quad K(x')=4.879$$

and from equation 1

$$C=2\varepsilon_0\frac{K(x')}{K(x)}=\frac{2(10^{-9})}{36\pi}\,\frac{4.879}{1.571}$$

$$=54.91 \text{ micromicrofarads per meter}$$

This result also can be obtained using the previously described approximations to the elliptic integrals and their moduli.

From equation 9

$$k_1=\left[\frac{1-2e^{-2\pi}}{1+2e^{-2\pi}}\right]^2=[(1-2e^{-2\pi})(1-2e^{-2\pi}+4e^{-4\pi}-\ldots)]^2$$
$$=1-8e^{-2\pi}+32e^{-4\pi}+\ldots$$
$$=0.98517$$

Again, from equation 2, x is found to be

$$x=\frac{k_2^2}{k_1^2}=\frac{1}{k_1^2}-1=0.03031$$

The ratio $K(x')/K(x)$ is determined from equation 6 with x replacing k

$$\frac{K(x')}{K(x)}=\frac{1}{\pi}\log_e 2(1+\sqrt{x'})/(1-\sqrt{x'})$$

$$=\frac{1}{\pi}\log_e\frac{2(1+\sqrt{x'})^2(1+x')}{x^2}$$

$$\frac{K(x')}{K(x)}=\frac{2}{\pi}\log_e(4/x) \text{ for } x \text{ near zero}$$

$$=\frac{2}{\pi}(4.883)$$

and from equation 1

$$C=2\varepsilon_0\frac{K(x')}{K(x)}=\frac{2(10^{-9})}{36\pi}\,\frac{2}{\pi}(4.883)$$

$$=54.97 \text{ micromicrofarads per meter}$$

II. An Approximate Solution

In the event that the exact solution described in Part I is not applicable, an approximate calculation, using conformal transformation methods, is possible in most cases. It is convenient, here again, to make use of symmetry and to consider the rectangular cylinder of Figure 1 to be composed of four "L" sections.

The most important and best known approximation to the finite "L" of Figure 3(A) is the infinite "L" (sides extend to infinity in both directions) of Figure 3(B). Historically this approximation was first used in estimating the additional capacitance in the bend of a Leyden jar. Jeans[9] uses this approximation to compute the capacitance of a finite "L" whose side lengths are large compared with the distances between the conductors.

When the side lengths are not large compared to these distances another procedure must be used. The lines of electric flux in the region near the bend have approximately the shape shown in Figure 3(B). Consider the particular section bounded by the flux lines $(H'D')$, $(G'F')$, and the conductors $(G'B'H')$ and $(D'E'F')$. If DE equals $D'E'$ and EF equals $E'F'$, then the capacitance of the section $G'B'H'D'E'F'G'$ will be less than that of the "L," $ABCDEFA$, and is accordingly designated $C_-/4$, where $C/4$ is the capacitance of the "L."

Similarly the capacitance of the section $A'B'C'I'E'J'A'$ will be greater than $C/4$ and is designated $C_+/4$. The four factor is included so that C may represent the capacitance of the rectangular coaxial cylinder of Figure 1 consisting of four "L" sections.

The transformation which maps the interior of the infinite "L" into the upper half of the t plane is

$$z=\frac{2}{\pi}\left[a\tan^{-1}\sqrt{\frac{\alpha^2t-1}{t+1}}+b\tanh^{-1}\frac{1}{\alpha}\sqrt{\frac{\alpha^2t-1}{t+1}}\right] \tag{10}$$

where

$$\alpha=a/b$$

The correspondence between points

in the z plane and the transformed points in the t plane is indicated in Figure 3; the primed points of Figure 3(B) go into the double primed points of Figure 3(C). The curved flux lines in the z plane transform into the semicircles in the t plane.

The points E'' and B'' correspond to $t=-1$ and $t=1/\alpha^2$ respectively. Let η, λ, ρ, and μ represent the particular values of t at the points A'', C'', D'', and F'' respectively. To determine C_+ and C_- it is necessary to compute these constants. This is done with the aid of the transformation (equation 10). For example, μ is given by the solution of the equation

$$(BA)+jb=\frac{2}{\pi}\left[a\tan^{-1}\sqrt{\frac{\alpha^2\mu-1}{\mu+1}}+b\tanh^{-1}\frac{1}{\alpha}\sqrt{\frac{\alpha^2\mu-1}{\mu+1}}\right] \quad (11)$$

It should be observed that η, λ, ρ, and μ are bounded by the relations

$$\begin{aligned} -\infty<\mu<-1 \qquad & 0<\lambda<1/\alpha^2 \\ -1<\rho<0 \qquad & 1/\alpha^2<\eta<+\infty \end{aligned} \quad (12)$$

The transformation

$$w=u+jv=\log_e t \quad (13)$$

maps the upper half of the t plane into the infinite strip between $v=0$ and $v=\pi$ in the w plane, with the positive real axis going into $v=0$ and the negative real axis into $v=\pi$. $C_+/4$ and $C_-/4$ are readily determined in the w plane since they are simply sections of an infinite parallel-plate capacitor.

The capacitance approximations C_+ and C_- are therefore obtained from the expressions

$$C_+=\frac{4\varepsilon_0}{\pi}\log_e(\eta/\lambda);\ C_-=\frac{4\varepsilon_0}{\pi}\log_e(\mu/\rho) \quad (14)$$

C_+ and C_- provide upper and lower bounds for C, the capacitance per meter of the cylinder of Figure 1, and therefore permit the calculation of maximum error. An average value of C_+ and C_- provides a better approximation since the uncertainty of the answer is reduced by a factor of two.

Example

Consider the calculation of C_- for the square coaxial cylinder of the previous example whose sides have a ratio $[(AB)/(EF)]=3.0$. From equation 14 μ and ρ are to be determined. Substituting in equation 11, $\alpha=(a/b)=1$ and $a=b=(AB)-(EF)$, we find

$$\left[\frac{(AB)}{(AB)-(EF)}+j\right]\frac{\pi}{2}=\tan^{-1}\delta+\tanh^{-1}\delta \quad (15)$$

where

$$\delta=\sqrt{\frac{|\mu|+1}{|\mu|-1}}>1 \text{ since } -\infty<\mu<-1 \quad (16)$$

The $\tanh^{-1}\delta$ may be evaluated from the identity

$$\tanh^{-1}\delta=\frac{1}{2}\log_e\frac{(1+\delta)}{(1-\delta)}=\frac{1}{2}\log_e\frac{(\delta+1)}{(\delta-1)}+\frac{j\pi}{2}+j\pi m \quad (17)$$

where m is an integer. It must be chosen so as to select the correct branch of the multiple valued arc hyperbolic tangent. Substituting equation 17 in equation 15, we obtain

$$\left[\frac{3}{2}+j\right]\frac{\pi}{2}=\tan^{-1}\delta+\frac{1}{2}\log_e\frac{(\delta+1)}{(\delta-1)}+\frac{j\pi}{2} \quad (18)$$

for $m=0$. This is a real, transcendental equation in δ which must be solved by approximation methods.

Solution gives

$\delta=1.09979$
$\mu=-10.54$

The equation corresponding to equation 11 for ρ is, after substituting $\alpha=1$ and $a=b=(AB)-(EF)$

$$\left[1+j\frac{(BC)}{(AB)-(EF)}\right]\frac{\pi}{2}=\tan^{-1}(j\gamma)+\tanh^{-1}(j\gamma) \quad (19)$$
$$=\tan^{-1}(j\gamma)+j\tan^{-1}\gamma$$

where

$$\gamma=\sqrt{\frac{1+|\rho|}{1-|\rho|}}>1 \text{ since } -1<\rho<0 \quad (20)$$

The $\tan^{-1}(j\gamma)$ is evaluated using

$$\tan^{-1}(j\gamma)=j\tanh^{-1}\gamma=\frac{j}{2}\log_e\frac{(1+\gamma)}{(1-\gamma)}$$
$$=\frac{j}{2}\log_e\frac{(\gamma+1)}{(\gamma-1)}+\frac{j}{2}(j\pi+j2\pi n) \quad (21)$$

Substituting equation 21 in equation 19 gives

$$\left[1+j\frac{3}{2}\right]\frac{\pi}{2}=\frac{j}{2}\log_e\frac{(\gamma+1)}{(\gamma-1)}-\frac{\pi}{2}(2n+1)+j\tan^{-1}\gamma \quad (22)$$

for which $n=-1$ selects the desired branch of the arc tangent. Equation 22 in γ is the same equation as 18 in δ, so that $\gamma=\delta$, and from equations 16 and 20 $\rho=1/\mu$. From equation 14

$$C_-=\frac{4\varepsilon_0}{\pi}\log_e\mu^2=\frac{8(10^{-9})}{36\pi^2}\log_e(10.54)$$
$$=52.9 \text{ micromicrofarads per meter}$$

Another Approximate Method

Another method of approximating the finite "L" problem using conformal transformations is given in a paper by Cockcroft.[18] This method requires that only one pair of sides go to infinity. While it is less restrictive than the method pre-

Figure 2 (left). (A) "L" section of Figure 1. Region "G" is mapped successively into: (B) real axis and upper half of t plane; (C) real axis and upper half of τ plane; (D) rectangular region R of w plane

5.62	34.1	39.1	29.2	34.2	37.6	

*These values were not determined directly but were computed from an empirical formula based on other measurements.[11]

sented, it appears to be much more difficult to apply.

III. Comparison of Calculated and Experimentally-Determined Values of Capacitance

Capacitance calculations, using the methods of Parts I and II, were performed for several cases of square cross-sections; that is, $(AB)=(BC)$ and $(DE)=(EF)$. Table I shows these values compared with the experimentally-determined values of Higgins and Teasdale.[11] The latter were derived from resistance measurements based on the mathematical equivalence of the electrostatic and current flow fields.

The final column shows values of capacitance as computed by a relaxation process. These values were used by the authors[12] as check points. It is to be noted that the capacitance values determined by experiment are all above the calculated values and are also above the values determined by relaxation process.

The approximation method of Part II yields surprisingly good results when the average of C_+ and C_- is used. In the case where the sides are in the ratio 5.62-to-1 the average value of capacitance is still very close to the correct value.

Appendix

Summary of Previous Work

The transformation

$$z=\alpha\int_0^t \frac{dt}{\sqrt{t(1+\eta t)(1+\lambda t)(1-t)(1-\rho t)}} \tag{23}$$

maps the upper half of the t plane in Figure 2(B) into the region G, Figure 2(A), in the z plane, and carries the points A', B', C', D', F' into the corresponding points A, B, C, D, F and the infinite point into E.

The difficulty in applying the method attends the determination of the branch points of the integral η, λ, and ρ and the evaluation of the integral in terms of known functions. Bergman,[8,9] using a theorem due to Jacobi, has reduced the hyperelliptic integral (equation 23) to two elliptic integrals of the first kind for the special case where the branch points satisfy the relation

$$\rho=\eta\lambda \tag{24}$$

Using the successive transformations

$$p=(1+\eta\lambda t^2)/t \tag{25}$$

and

$$r^2=\frac{p-(1+\eta\lambda)}{p-2\sqrt{\eta\lambda}};\quad s^2=\frac{p-(1+\eta\lambda)}{p+2\sqrt{\eta\lambda}} \tag{26}$$

the integral (equation 23) is reduced to

$$z=\frac{\alpha}{2}\left[\int_{r_0}^{r}\frac{dr}{\sqrt{(1-r^2)(1-k_1^2r^2)}}+\int_{s_0}^{s}\frac{ds}{\sqrt{(1-s^2)(1-k_2^2s^2)}}\right] \tag{27}$$

where

$$k_1^2=\frac{(\sqrt{\eta}+\sqrt{\lambda})^2}{(1+\eta)(1+\lambda)};\quad k_2^2=\frac{(\sqrt{\eta}-\sqrt{\lambda})^2}{(1+\eta)(1+\lambda)} \tag{28}$$

As t varies from $-\infty$ to $+\infty$ along the real axis the point in the z plane moves around the boundary of the "L." The sides of the "L" are related to the elliptic integrals of the first kind from equation 27. The moduli k_1 and k_2 are therefore determined by the dimensions of the "L." The relations are

$$\frac{K(k_1)}{K(k_1')}=2\left[\frac{(AB)-(CD)/2}{(AF)}\right];$$
$$\frac{K(k_2)}{K(k_2')}=\frac{1}{2}\left[\frac{(DC)}{(BC)-(AF)/2}\right] \tag{29}$$

To satisfy equation 24 it is necessary that k_1, k_2 and the sides of the "L" satisfy

$$\frac{K(k_2)}{K(k_1')}=\frac{(DC)}{(AF)} \tag{30}$$

Application to the Capacitance Problem

Since the preceding transformations are conformal, they can be applied to the capacitance problem. In this problem, as explained earlier, ABC and DEF are equipotentials and CD and AF are lines of electric flux. To determine the capacitance we must retransform the upper half of the t plane into the interior of the region R of the w plane of Figure 2(D). To facilitate the final transformation, it is convenient first to transform the upper half of the t plane into the corresponding region of the τ plane using the transformation

$$v=\frac{(\sqrt{\lambda}+\sqrt{\eta})(1+\sqrt{\eta\lambda}t)}{(\sqrt{\lambda}-\sqrt{\eta})(1-\sqrt{\eta\lambda}t)} \tag{31}$$

The correspondence between points in the two planes is indicated in Figure 2; the primed points in Figure 2(B) go into the double primed points in Figure 2(C).

The upper half of the τ plane is finally mapped into the rectangular region R, Figure 2(D), in the w plane by the transformation

$$w=\int_0^{\tau}\frac{d\tau}{\sqrt{(1-\tau^2)(1-x^2\tau^2)}} \tag{32}$$

The modulus, x, of the elliptic integral (equation 32) is determined in terms of the original branch points η and λ from

$$x^2=\left[\frac{1-\sqrt{\eta\lambda}}{1+\sqrt{\eta\lambda}}\right]\left[\frac{\sqrt{\lambda}-\sqrt{\eta}}{\sqrt{\lambda}+\sqrt{\eta}}\right]^2 \tag{33}$$

Using equations 28 and 33, x is expressible in terms of k_1 and k_2 as

$$x^2=\frac{k_2^2(1-k_1^2)}{k_1^2(1-k_2^2)} \tag{34}$$

Since capacitance is invariant under the conformal transformations, the capacitance per unit length of the "L" of Figure 2(A), is equal to that of the parallel-plate capacitor of Figure 2(D). There are four "L's" in parallel making up the cylindrical capacitor of Figure 1. Therefore

$$C=4\epsilon_0\left[\frac{K(x')}{2K(x)}\right]=2\epsilon_0\frac{K(x')}{K(x)} \tag{35}$$

gives the capacitance per meter of coaxial cylinders of rectangular cross-section.

A New Device for Calibrating Watt-Hour Meters

H. F. ROBISON
MEMBER AIEE

W. H. WICKHAM
MEMBER AIEE

A NEW device has been developed to provide a better means of calibrating watt-hour meters, particularly in the field. With this device the field testing of watthour meters is made much faster and easier as compared to the conventional methods of counting or timing of disk revolutions. It is faster because an instantaneous and continuous visual indication of meter accuracy is obtained. It is easier because the indication is definite and clear. The tester is subjected to less eye strain than in the close observation of meter disks. In general, closer adjustment to correct registration is obtained than by the methods involving successive trials. The device is portable. No special disks, disk markings, or the like are required for its application.

Other methods, such as the stroboscopic methods and automatic counting of revolutions, have been developed for laboratory and shop use and have some of the same advantages. While these methods are a great improvement over the conventional methods of counting or timing of disk revolutions, they are not applicable to field testing because they require that the meters be mounted in a special stand, or jig, and furthermore, the equipment is too elaborate and cumbersome.

The new device compares the speed of the disk of the meter under test with that of a standard watt-hour meter by photoelectric means. An instantaneous and continuous comparison of speeds is indicated on the screen of a cathode-ray tube.

Both the standard and test watt-hour meters are equipped with a light source, a system of lenses and mirrors, and a photocell. Serrations on the disk of each meter interrupt the light on the photocells as the disks rotate. Serrated disks are standard on most modern watt-hour meters. The variation of current in the photocell on the standard meter is utilized to control the horizontal sweep circuit of a cathode-ray tube, and on the test meter to produce a vertical deflection on the screen of the cathode-ray tube. The resulting trace is stationary when the disks of both meters are rotating at the same speed, and moves across the screen when the two speeds differ. The action of the trace is used to obtain an "as found" check by varying the voltage on the standard to match its speed to that of the meter under test. It also is used to obtain correct registration of the meter under test by varying the speed of that meter, by adjustment, to match the speed of the standard.

Description of Device

The standard watthour meter is permanently equipped with an optical system and photocell. For the test meter, a spare cover of the type on the meter under test is equipped with a bracket on which a similar optical system and photocell can be mounted. This cover temporarily replaces the regular meter cover for test purposes. This optical system is shown in Figure 1(A). Light is directed by lenses and mirrors along the path indicated by the dotted lines to project an enlarged image of the disk teeth on the light shield of the photocell. The holes in this shield are in a horizontal line and are spaced so that the distances between centers of the holes are equal to the distances between centers of the magnified tooth images. Figure 1(B) is a section of watt-hour meter disk showing the toothed edge and Figure 1(C) is a section of the light shield of the photocell showing the holes with the disk tooth images superimposed. As the watt-hour meter disk revolves, the holes in the light shield of the photocell are alternately covered and uncovered by the disk tooth images. This causes the photocell to pass a periodic current, the frequency of which is proportional to the speed of rotation of the watt-hour meter disk.

The photocells used in this apparatus also are electron multipliers. The periodic photocell currents are passed through suitable resistors to produce periodic voltages. The method of comparison of the frequencies of the voltage waves from the test unit on the standard meter and from the test unit on the meter under test is shown in a block diagram in Figure

Figure 2 (left). Block diagram of electronic circuit

Figure 3 (right). Test connections for calibration of watt-hour meter

2. The periodic voltage from the test unit on the standard meter is amplified by an impedance-matching amplifier and used to synchronize the adjustable frequency linear sweep circuit. Thus the sweep frequency of the trace on the cathode-ray tube is controlled by the disk speed of the standard meter. The voltage from the test unit on the meter under test is amplified and impressed on the vertical deflection plates of the cathode-ray tube. In this way a single wave is produced on the screen of the tube that remains stationary when the disks of the two watt-hour meters are running at the same speed. When the disk speeds differ, the wave will travel across the screen in a horizontal direction. The direction of travel indicates whether the test meter is running faster or slower than the standard. Note that, because of "anti-creep" holes, the speed of a watt-hour meter disk is not constant throughout a revolution. Because of this variation in speed the wave will not remain perfectly stationary, but will move back and forth, and equal average speeds are indicated by zero net travel of the wave. This effect is more noticeable at the lower disk speeds, but in no case does it seriously impair the accuracy. A difference of 0.1 per cent in disk speeds can be detected. Since the cathode-ray oscilloscope is used as a null detector, that is, to detect zero difference in disk speeds, the accuracy of detection is independent of the calibration of the detector. It is not essential that the frequencies of the periodic voltages produced by the rotation of the two disks be the same since the latitude of adjustment of the resistance-capacitance components in the sweep circuit is sufficient to permit adjustment to one-half or one-third of the frequency of the voltage from the standard meter. The sweep will then lock at every second or third cycle of the voltage from the standard. Conversely, if the frequency of the voltage from the test meter is an integral multiple of the frequency of the voltage from the standard, such as 2 or 3 and so forth, 2 or 3 cycles will appear on the cathode-ray screen. This permits the use of the same standard meter to calibrate meters having different numbers of disk teeth and different disk constants.

In order to vary the speed of the disk of the standard watt-hour meter to match the speed of the disk of the meter under test as required for an "as found" check, the potential coil of the standard is energized through a combination of two autotransformers, one tapped, and one continuously variable as shown in Figure 3. The main autotransformer has three taps spaced at $2^1/_2$ per cent intervals each side of the 100 per cent point. The auxiliary autotransformer can be connected across alternate taps of the main autotransformer by a tap switch as shown, so that the voltage impressed on the standard meter can be varied from $92^1/_2$ per cent to $107^1/_2$ per cent of the voltage impressed on the meter under test. The tap switch on the main transformer and the dial on the auxiliary transformer are calibrated in per cent voltage impressed on the standard, which is the same as per cent registration of the meter under test. The phase angles of the autotransformers have been measured and found to be negligible, therefore the same scale markings on the dials are used for loads at unity and 50 per cent power factors, the usual check points.

All equipment necessary to calibrate a watt-hour meter by this method, except the adjustable load, is installed in one metal case. This includes the standard watt-hour meter with the optical system attached, the ammeter, the two autotransformers and the electronic detecting equipment. The test unit for use on the watt-hour meter under test is equipped with a flexible lead and polarized plug to be plugged into the side of the case. Figure 4 shows the top panel of this metal case along with the optical system, or test unit, to be attached to the meter under test.

Operation of Device

The operation of the device is very simple and with a small amount of practice, the meter tester is able to calibrate watt-hour meters quickly and accurately. Figure 5 shows the calibrating device with the test unit mounted on a switchboard meter and with all connections made for calibration. With the device connected as shown in Figure 5 for calibration at a desired load point, or speed, the test unit on the meter under test is positioned so as to produce maximum vertical deflection on the cathode-ray screen. The frequency of the sweep circuit is adjusted to approximate the frequency of the periodic voltage produced by the rotation of the disk of the standard, at which point the synchronizing voltage from the standard controls the frequency of sweep. The "as found" check on the meter being tested is obtained by adjusting the speed of the standard to the speed of the test meter as indicated by a stationary trace on the cathode-ray screen. The per cent registration of the meter under test is then read directly from the dials of the autotransformers.

If the "as found" check shows a need for adjustment of the meter being tested, the dials of the autotransformers are set for the desired registration, taking into account the ratio correction factors of the instrument transformers supplying the meter being tested, and the calibration of the standard watt-hour meter. This will cause the trace on the screen of the cathode-ray tube to travel across the screen, the direction of travel depending on whether the meter being tested is faster or slower than the standard. The trace on the screen is again brought to a stationary position by changing the adjustments on the meter being tested.

Operating Experience

The new watt-hour meter calibrating device has been used for calibrating sta-

Figure 4 (left). Panel view of device

Figure 5 (right). Device connected for watt-hour meter calibration

tion meters for a period of about eight months. In this time it has been found that accurate calibration by this method requires only one-third as much time as the conventional method of counting revolutions. The device detects erratic disk motion such as caused by defective bearings or by foreign material on the disks or magnets much more readily than the conventional method. It has been found that the tester can observe the action of the trace on the cathode-ray screen over long periods of time with no appreciable eye strain.

The sensitivity of the detecting device is such that meters can be calibrated with an accuracy of 0.1 per cent. Numerous checks have been made in the laboratory comparing the accuracy of the new method against the conventional method of counting revolutions. It has been found that these methods are within 0.1 per cent of agreement.

Watt-hour meter adjustments are more accurately made with this new device because the meter under test is adjusted accurately to the desired registration on the first trial rather than within previously established limits after successive trials.

Equivalent Circuits of the Shaded-Pole Motor with Space Harmonics

GABRIEL KRON
MEMBER AIEE

EQUATIONS and equivalent circuits are developed for the shaded-pole motor including the space-harmonics introduced by the stator windings. Uneven airgap, also an impressed voltage on the shaded coil are assumed, while the parameters include the ratio of turns and the angle of shift of the shaded coil. The equations and equivalent circuits cover both the cross-field and the revolving-field theories.

Derivation from the Primitive Machine

There are at least four different points of view in which a shaded-pole motor may be assumed to differ from a split-phase induction motor with uneven airgap, or rather from the primitive machine with three stator windings, Figure 1.

1. The shaded pole is represented by a winding shifted by an angle α from the direct axis, Figure 2(A).

2. The shaded pole is assumed to be wound on both axes, in particular with $\cos\alpha$ turns on the direct axis and with $\sin\alpha$ turns on the quadrature axis, Figure 2(B).

3. The main winding is shifted by an angle α, Figure 2(C).

4. The main winding is wound on both axes, Figure 2(D).

It will be shown that the first two (or last two) points of view may be so treated as to be indistinguishable from each other. The writer in a previous publication (reference 10, page 47) followed the first point of view. Here the same method will be extended to be reducible to equivalent circuits.

Reactance Calculation of the Shaded Coil

The shaded coil lies at an angle α from the main-pole axis (direct axis). The reactances are calculated in the following manner:

1. The shaded coil is assumed to lie at first in the direct axis, $\alpha=0$, Figure 3(A).

Its leakage reactance x_{ds1}, its mutual leakage reactance with the main-pole winding is x_{mds} and its mutual reactance with the rotor is X_{md}.

2. The shaded coil is assumed to lie next in the quadrature axis, $\alpha=90°$ Figure 3(B). Its leakage reactance is x_{qs1} which may be different from x_{ds1} and its mutual reactance with the rotor is X_{mq}, which may be different from X_{md}.

Its resistance in either axis is r_{s1}. Also the shaded coil is assumed to have the same number of turns as the main pole winding (and the rotor). Any difference in their turn ratio, also any outside impedance in series with the shaded coil will enter into the analysis later on.

The Sequence of Steps

The following steps will be made in the derivation of the equivalent circuits:

1. First the equation of the actual shaded pole motor with windings at an angle α are derived, using the cross-field theory.

2. Next the actual machine is replaced by an equivalent split-phase induction motor whose windings are at right angles from each other. The reactances of this hypothetical motor are expressed in terms of those of the shaded-pole motor assuming the angle of shift "α" and the ratio of turns "α" as parameters. Its equations in the cross-field theory are found.

3. The equations of the equivalent motor in the revolving-field theory are found.

4. The equivalent circuit of the hypothetical motor are found by the revolving-field theory.

5. The equivalent circuits in the cross-field theory are developed.

6. The presence of space-harmonics is considered in both types of equivalent circuits.

Part I. Equations of the Actual Machine

The Primitive Machine

Let it be assumed that two identical shaded coils exist on the stator, in particular one along the direct axis (d_{s1}) and one along the quadrature axis (q_{s1}). Then the Z of the primitive machine (Figure 1) with three stator and two rotor windings (each having the same number of turns) is

$$Z=\begin{array}{c|c|c|c|c|c|}
 & d_{s2} & d_{s1} & q_{s1} & d_r & q_r \\
\hline
d_{s2} & r_{ds2}+jX_{ds2} & jX_{ms} & & jX_{md} & \\
\hline
d_{s1} & jX_{ms} & r_{s1}+jX_{ds1} & & jX_{md} & \\
\hline
q_{s1} & & & r_{s1}+jX_{qs1} & & jX_{mq} \\
\hline
d_r & jX_{md} & jX_{md} & X_{mq}v & r_r+jX_{dr} & X_{qr}v \\
\hline
q_r & -X_{md}v & -X_{md}v & jX_{mq} & -X_{dr}v & r_r+jX_{qr} \\
\hline
\end{array} \qquad (1)$$

The coefficients of v are the torsion tensor G

$$G=\begin{array}{c|c|c|c|c|c|}
 & d_{s2} & d_{s1} & q_{s1} & d_r & q_r \\
\hline
d_r & & & X_{mq} & & X_{qr} \\
\hline
q_r & -X_{md} & -X_{mc} & & -X_{dr} & \\
\hline
\end{array}$$

Figure 2 (right). Four different points of view of the shaded-pole motor

In terms of leakage reactances x_{ds1}, x_{ds2}, x_{dsm}, x_{qs1}, X_{md}, X_{mq}, x_r (Figure 3) the self-inductances are defined as

$$\begin{aligned} X_{ds2} &= X_{md}+x_{ds2} & X_{ms} &= X_{md}+x_{dsm} \\ X_{ds1} &= X_{md}+x_{dsm}+x_{ds1} & X_{dr} &= X_{md}+x_r \\ X_{qs1} &= X_{mq}+x_{qs1} & X_{qr} &= X_{mq}+x_r \end{aligned} \qquad (2)$$

The equations of the primitive machine are $\boldsymbol{e}=\boldsymbol{Z}\boldsymbol{i}$ and $T=\boldsymbol{i}^*\boldsymbol{G}\boldsymbol{i}=\boldsymbol{i}^*\boldsymbol{B}$ where $\boldsymbol{B}=\boldsymbol{G}\boldsymbol{i}$.

The Actual Machine

In going from the primitive machine to the actual machine, two different points of view may be used, each leading to the same set of equations:

1. Let only one shaded coil exist shifted by an angle α from the direct axis, Figure 2(A) and having "a" number of turns where

$$a=\frac{\text{Number of turns of shaded coil}}{\text{Number of turns of main winding}}$$

The relation between the old and new currents are $\boldsymbol{i}=\boldsymbol{C}_1\boldsymbol{i}_1$ where

$$\boldsymbol{C}_1=\begin{array}{c|c|c|c|c|}
 & m & s & d_r & q_r \\ \hline
d_{s2} & 1 & & & \\ \hline
d_{s1} & & a\cos\alpha & & \\ \hline
q_{s1} & & a\sin\alpha & & \\ \hline
d_r & & & 1 & \\ \hline
q_r & & & & 1 \\ \hline
\end{array} \qquad (3)$$

By $\boldsymbol{C}_{1t}\boldsymbol{Z}\boldsymbol{C}_1$ the new impedance matrix and torque tensor are

$$\boldsymbol{Z}_1=\begin{array}{c|c|c|c|c|}
 & m & s & d_r & q_r \\ \hline
m & r_{ds2}+jX_{ds2} & jX_{ms}a\cos\alpha & jX_{md} & \\ \hline
s & jX_{ms}a\cos\alpha & a^2r_{s1}+jX_{ds1}a^2\cos^2\alpha+jX_{qs1}a^2\sin^2\alpha & jX_{md}a\cos\alpha & jX_{mq}a\sin\alpha \\ \hline
d_r & jX_{md} & jX_{md}a\cos\alpha+X_{mq}v\,a\sin\alpha & r_r+jX_{dr} & X_{qr}v \\ \hline
q_r & -X_{md}v & jX_{mq}a\sin\alpha-X_{md}v\,a\cos\alpha & -X_{dr}v & r_r+jX_{qr} \\ \hline
\end{array} \qquad (4)$$

$$\boldsymbol{G}_1=\begin{array}{c|c|c|c|c|}
 & m & s & d_r & q_r \\ \hline
d_r & & X_{mq}\,a\sin\alpha & & X_{qr} \\ \hline
q_r & -X_{md} & -X_{md}\,a\cos\alpha & -X_{dr} & \\ \hline
\end{array}$$

The current vector is

$$\boldsymbol{i}_1=\begin{array}{c|c|c|c|}
m & s & d_r & q_r \\ \hline
i^m & i^s & i^{dr} & i^{qr} \\ \hline
\end{array} \qquad (5)$$

where i^s is the actual shaded-coil current and i^m the main-winding current. The impressed-voltage vector is

$$\boldsymbol{e}_1=\begin{array}{c|c|c|c|}
m & s & d_r & q_r \\ \hline
e_m & e_s & 0 & 0 \\ \hline
\end{array} \qquad (6)$$

where e_s is the actual shaded-coil impressed voltage and e_m is the main-winding impressed voltage.

2. Let two shaded coils exist. One, along the direct axis, has $a\cos\alpha$ turns, the other, along the quadrature axis, has $a\sin\alpha$ turns (Figure 1). Then

$$\boldsymbol{C}_1'=\begin{array}{c|c|c|c|c|}
 & d_{s2}' & d_{s1}' & q_{s1}' & d_r' & q_r' \\ \hline
d_{s2} & 1 & & & & \\ \hline
d_{s1} & & a\cos\alpha & & & \\ \hline
q_{s1} & & & a\sin\alpha & & \\ \hline
d_r & & & & 1 & \\ \hline
q_r & & & & & 1 \\ \hline
\end{array} \qquad (7)$$

$$\boldsymbol{C}_1''=\begin{array}{c|c|c|c|c|}
 & m & s & d_r & q_r \\ \hline
d_{s2}' & 1 & & & \\ \hline
d_{s1}' & & 1 & & \\ \hline
q_{s1}' & & 1 & & \\ \hline
d_r' & & & 1 & \\ \hline
q_r' & & & & 1 \\ \hline
\end{array} \qquad (8)$$

Performing simultaneously the two transformations the resultant matrix

$$\boldsymbol{C}_1=\boldsymbol{C}_1'\boldsymbol{C}_1'' \qquad (9)$$

is identical with $\boldsymbol{C}_1$. Hence the two points of view of Figures 2(A) and 2(B) are indistinguishable from each other mathematically.

The equations $\boldsymbol{e}_1=\boldsymbol{Z}_1\boldsymbol{i}_1$ and $T=\boldsymbol{i}_1^*\boldsymbol{G}_1\boldsymbol{i}_1$ represent the basic equations of the shaded pole motor in the cross-field theory, as given by the author in reference 10 (the same equations also appear in reference 9). The equations of references 3, 4, and 5 are also of the same general nature. All these equations have the disadvantage that the d and q axes are all mixed up in them. Hence they are not well adapted for the introduction of symmetrical components nor for the development of equivalent circuits.

The two coils are connected in series, Figure 2(B) by

Replacing Currents of Individual Windings by Resultant Magnetomotive Forces Along the Axes

The equations may be brought to a simpler, more practical and also more familiar form by replacing the actual winding currents i^m and i^s by another set of variables i^{ds} and i^{qs}

$$i^{ds} = i^m + i^s a \cos \alpha$$
$$i^{qs} = i^s a \sin \alpha \tag{10}$$

representing the resultant direct-axis magnetomotive force of both windings and the quadrature-axis magnetomotive force of the shaded coil respectively. That is, let the inverse matrix of transformation be

$$C_s^{-1} = \begin{array}{c|cc|c|c|} & m & s & d_r & q_r \\ \hline d_s & 1 & a\cos\alpha & & \\ q_s & & a\sin\alpha & & \\ \hline d_r & & & 1 & \\ q_r & & & & 1 \\ \hline \end{array} \tag{11}$$

Then its inverse is

$$C_s = \begin{array}{c|cc|c|c|} & d_s & q_s & d_r & q_r \\ \hline m & 1 & -\cot\alpha & & \\ s & & 1/(a\sin\alpha) & & \\ \hline d_r & & & 1 & \\ q_r & & & & 1 \\ \hline \end{array}$$

$$i^m = i^{ds} - i^{qs} \cot \alpha$$
$$i^s = i^{qs}/(a \sin \alpha) \tag{12}$$

where i^s is the shaded-coil current (it should be noted that in the special case when $\alpha = 0$ then $\sin \alpha = 0$ and C_s has no existence. Hence the following equations are not valid in the special case when $\alpha = 0$).

By $C_s Z_1 C_s$, $C_s G_1 C_s$ and $C_s e_1$,

$$Z_s = \begin{array}{c|c|c|c|c|} & d_s & q_s & d_r & q_r \\ \hline d_s & r_{ds1} + jX_{ds1} & -(r_{ds2} + jx_{ds2}) \cot \alpha & jX_{md} & \\ q_s & -(r_{ds2} + jx_{ds2}) \cot \alpha & \begin{array}{c} r_{qs1} + jX_{qs1} + \\ (r_{ds2} + jx_{ds2} + \\ r_{ds2} + jx_{ds2}) \cot^2 \alpha \end{array} & & jX_{mq} \\ d_r & jX_{md} & X_{mq}v & r_r + jX_{dr} & X_{qr}v \\ q_r & -X_{md}v & jX_{mq} & -X_{dr}v & r_r + jX_{qr} \\ \hline \end{array} \tag{13}$$

$$G_s = \begin{array}{c|c|c|c|c|} & d_s & q_s & d_r & q_r \\ \hline d_r & & X_{mq} & & X_{qr} \\ q_r & -X_{md} & & -X_{dr} & \\ \hline \end{array}$$

$$e_s = \begin{array}{c|c|c|c|c|} & d_s & q_s & d_r & q_r \\ \hline & e_m & e_s/(a\sin\alpha) - e_m \cot\alpha & & \\ \hline \end{array} \tag{14}$$

Reactances of the Equivalent Split-Phase Motor

The equations of the shaded-pole motor with stator windings at an angle α, Figure 4(A), have hereby been brought to the form of those of an unsymmetrical split-phase induction motor having windings along the direct and quadrature axes, Figure 4(B). The only difference is that now mutual impedances exist between the two stator windings at right angles in space.

The equivalence is made clearer by replacing the actual shaded-pole machine reactances by those of the equivalent split-phase motor. (The latter will be denoted by a prime.) Only the stator resistances and leakage reactances are different, the airgap and rotor quantities are identical. In particular, Figure 4(C)

$$r_{ds}' = r_{ds2}(1 - \cot \alpha)$$
$$x_{ds}' = x_{ds2}(1 - \cot \alpha) + x_{dms}$$
$$r_{qs}' = r_{qs1} + r_{ds1} \cot^2 \alpha + r_{ds2} \cot \alpha (\cot \alpha - 1)$$
$$x_{qs}' = x_{qs1} + x_{ds1} \cot^2 \alpha + x_{ds2} \cot \alpha (\cot \alpha - 1)$$
$$z_m' = (r_{ds2} + jx_{ds2}) \cot \alpha \tag{15}$$

It should be noted that the angular shift α appears only as a single ratio of turns

$$\cot \alpha = b = \frac{\cos \alpha}{\sin \alpha} = \frac{\text{number of turns on direct axis}}{\text{number of turns on quadrature axis}}$$

Equations of the Equivalent Split-Phase Motor

In terms of the primed reactances Z_2 of the equivalent motor becomes

$$Z_2 = \begin{array}{c|c|c|c|c|} & d_s & q_s & d_r & q_r \\ \hline d_s & r_{ds}' + jX_{ds}' + z_m' & -z_m' & jX_{md} & \\ q_s & -z_m' & r_{qs}' + jX_{qs}' + z_m' & & jX_{mq} \\ d_r & jX_{md} & X_{mq}v & r_r + jX_{dr} & X_{qr}v \\ q_r & -X_{md}v & jX_{mq} & -X_{dr}v & r_r + jX_{qr} \\ \hline \end{array} \tag{16}$$

$$e_2 = \begin{array}{c|c|c|c|c|} & d_s & q_s & d_r & q_r \\ \hline & e_{ds} & e_{qs} & & \\ \hline \end{array}$$

In terms of the known actual motor impressed voltages e_m and e_s the voltages to be impressed on the equivalent motor are

$$e_{ds} = e_m$$
$$e_{qs} = e_s/(a \sin \alpha) - e_m \cot \alpha \tag{18}$$

$$i_2 = \begin{array}{c|c|c|c|c|} & d_s & q_s & q_r & q_r \\ \hline & i^{ds} & i^{qs} & i^{dr} & i^{qr} \\ \hline \end{array} \tag{19}$$

In terms of actual motor currents i^m and i^s

$$i^{ds} = i^m + i^s a \cos \alpha$$
$$i^{qs} = i^s a \sin \alpha \tag{20}$$

Hence, if the equations $e_2 = Z_2 i_2$ of the equivalent motor are solved for i_2 then the actual machine currents are found from those of the equivalent motor by

$$i^m = i^{ds} - i^{qs} \cot \alpha$$
$$i^s = i^{qs}/(a \sin \alpha) \tag{21}$$

These equations are identical with those of a split-phase induction motor (or of the primitive machine having two stator and two rotor windings) with the following complications:

1. The two stator windings have an additional self and mutual impedance equal to z_m'.
2. The airgap is unequal along the two axes.

The Revolving Field Theory

Since the losses in the rotor of induction motors are mostly of double frequency, it is useful to set up the equations along the symmetrical component (forward and backward) axes.

If the following matrix of transformation is assumed

$$C_3 = \begin{array}{c|c|c|} & s & r \\ \hline s & C_s & \\ r & & C_s \\ \hline \end{array} \qquad C_s = \frac{1}{\sqrt{2}} \begin{array}{c|c|c|} & f & b \\ \hline d & 1 & 1 \\ q & -j & j \\ \hline \end{array} \tag{22}$$

$$G_3 = \begin{array}{c|c|c|c|c|} & d_s & q_s & d_r & q_r \\ \hline d_r & & X_{mq} & & X_{qr} \\ q_r & -X_{md} & & -X_{dr} & \\ \hline \end{array} \tag{17}$$

then the formula $C_3^*, Z_3 C_3$ gives the impedance matrix $Z_3 =$

	f_s	b_s	f_r	b_r
f_s	$\frac{Z_{ds}'+Z_{qs}'}{2}+z_m'$	$\frac{Z_{ds}'-Z_{qs}'}{2}-jz_m'$	$\frac{j(X_{md}+X_{mq})}{2}$	$\frac{j(X_{md}-X_{mq})}{2}$
b_s	$\frac{Z_{ds}'-Z_{qs}'}{2}+jz_m'$	$\frac{Z_{ds}'+Z_{qs}'}{2}+z_m'$	$\frac{j(X_{md}-X_{mq})}{2}$	$\frac{j(X_{md}+X_{mq})}{2}$
f_r	$(1-v)\frac{j(X_{md}+X_{mq})}{2}$	$(1-v)\frac{j(X_{md}-X_{mq})}{2}$	$r_r+(1-v)\frac{j(X_{dr}+X_{qr})}{2}$	$(1-v)\frac{j(X_{dr}-X_{qr})}{2}$
b_r	$(1+v)\frac{j(X_{md}-X_{mq})}{2}$	$(1+v)\frac{j(X_{md}+X_{mq})}{2}$	$(1+v)\frac{j(X_{dr}-X_{qr})}{2}$	$r_r+(1+v)\frac{j(X_{dr}+X_{qr})}{2}$

(23)

By $C_3^* e_2$ the impressed voltage vector is

$$e_3 = \frac{1}{\sqrt{2}} \begin{array}{cccc} f_s & b_s & f_r & b_r \\ \hline e_{ds}+je_{qs} & e_{ds}-je_{qs} & & \end{array} \qquad (24)$$

The coefficients of v (or $C_3^* G_2 C_3$) give the torsion tensor

$$G_3 = \begin{array}{c|cccc} & f_s & b_s & f_r & b_r \\ \hline f_r & \frac{-j(X_{md}+X_{mq})}{2} & \frac{-j(X_{md}-X_{mq})}{2} & \frac{-j(X_{dr}+X_{qr})}{2} & \frac{-j(X_{dr}-X_{qr})}{2} \\ b_r & \frac{j(X_{md}-X_{mq})}{2} & \frac{j(X_{md}+X_{mq})}{2} & \frac{j(X_{dr}-X_{qr})}{2} & \frac{j(X_{dr}+X_{qr})}{2} \end{array} \qquad (25)$$

The equations $e_3 = Z_3 i_3$ and $T = i_3^* G_3 i_3$ represent the basic equations of the shaded-pole motor in the revolving field theory. Again they are analogous to the equations of the split-phase motor with the generalizations mentioned.

Part II. Equations of the Equivalent Circuits

The Revolving Field Equivalent Circuit

In order to establish an equivalent circuit along the sequence axes it is necessary to reduce the currents and voltages in all meshes of the actual machine to the same frequency base by multiplying both Z_3 and e_3 (but not i_3 or G_3) by the inverse of the "absolute frequency tensor" n, representing the actual frequency of the currents with respect to the conductors in each winding.

$$n^{-1} = \begin{array}{c|cccc} & f_s & b_s & f_r & b_r \\ \hline f_s & 1 & & & \\ b_s & & 1 & & \\ f_r & & & 1/(1-v) & \\ b_r & & & & 1/(1+v) \end{array} \qquad (26)$$

Figure 4 (A, B, C, D). The equivalent split-phase induction motor at standstill

$e_{ds} = e_m$	$i^m = i^{ds} - i^{qs} \cot a$
$e_{qs} = \frac{e_s}{a \sin a} - e_m \cot a$	$i^s = \frac{i^{qs}}{a \sin a}$
$r'_{ds} = r_{ds2}(1-\cot a)$	
$x'_{ds} = x_{ds2}(1-\cot a) + x_{dsm}$	
$r'_{qs} = r_{qs1} + r_{ds1} \cot^2 a + r_{ds2} \cot a(\cot a - 1)$	
$x'_{qs} = x_{qs1} + x_{ds1} \cot^2 a + x_{ds2} \cot a(\cot a - 1)$	
$z'_m = (r_{ds2} + jx_{ds2}) \cot a$	

(D) RELATIONS BETWEEN ACTUAL AND EQUIVALENT MOTOR

Figure 3. Reactances of the shaded-pole motor

Figure 5. Equivalent circuit of the shaded-pole motor (revolving field theory)

Figure 6 (left). Equivalent circuit of the shaded-pole motor (cross-field theory)

Figure 7 (top right). Interconnection of three shaded-pole motors having P, $3P$, and $5P$ pair of poles

Figure 8 (center right). Arrangement for space harmonics

Figure 9 (lower right). Isolating stator from rotor meshes

The resultant impedance matrix and impressed voltage vector become by n^{-1} $\mathbf{Z}_3$ and $n^{-1}\mathbf{e}_3$

	f_s	b_s	f_r	b_r
f_s	$\frac{Z_{ds}'+Z_{qs}'}{2}+z_m'$	$\frac{Z_{ds}'-Z_{qs}'}{2}-jz_m'$	$\frac{j(X_{md}+X_{mq})}{2}$	$\frac{j(X_{md}-X_{mq})}{2}$
b_s	$\frac{Z_{ds}'-Z_{qs}'}{2}+jz_m'$	$\frac{Z_{ds}'+Z_{qs}'}{2}+z_m'$	$\frac{j(X_{md}-X_{mq})}{2}$	$\frac{j(X_{md}+X_{mq})}{2}$
f_r	$\frac{j(X_{md}+X_{mq})}{2}$	$\frac{j(X_{md}-X_{mq})}{2}$	$\frac{r_r}{1-v}+\frac{j(X_{dr}+X_{qr})}{2}$	$\frac{j(X_{dr}-X_{qr})}{2}$
b_r	$\frac{j(X_{md}-X_{mq})}{2}$	$\frac{j(X_{md}+X_{mq})}{2}$	$\frac{j(X_{dr}-X_{qr})}{2}$	$\frac{r_r}{1+v}+\frac{j(X_{dr}+X_{qr})}{2}$

(27)

$$e_4=\frac{1}{\sqrt{2}}\begin{array}{cccc} f_s & b_s & f_r & b_r \\ \hline \multicolumn{2}{|c|}{e_{ds}+je_{qs}} & \multicolumn{2}{c|}{} \end{array} \qquad (28)$$

The multiplication of $\mathbf{Z}_3$ by n^{-1} consists simply in dividing the third row by $1-v$ and the fourth row by $1+v$. Also $\mathbf{e}_4=\mathbf{e}_3$ and $\mathbf{G}_4=\mathbf{G}_3$.

The corresponding equivalent circuit is shown in Figure 5. The torque is found as usual by subtracting the negative sequence rotor losses from the positive sequence rotor losses. That is

$$T=i_4^*G_4i_4=i_4^*B_4 \qquad (29)$$

where the flux densities $\mathbf{B}_4$ appear in the equivalent circuit as voltages across the rotor resistances.

If the direction of rotation of the rotor (from d to q) is assumed to occur counterclockwise, then

$$e_4=\frac{1}{\sqrt{2}}\begin{array}{cccc} f_s & b_s & f_r & b_r \\ \hline \multicolumn{2}{|c|}{e_{ds}-je_{qs}} & \multicolumn{2}{c|}{e_{ds}+je_{qs}} \end{array}$$

Similarly

$$i^{fs}=\frac{i^{ds}-ji^{qs}}{\sqrt{2}}$$

and so on.

The Phase-Shifter

It should be noted that the expression $z^{m\prime}$ (representing a mutual impedance between the stator direct and quadrature axes) does not occur in a symmetrical manner in the upper left hand corner of $\mathbf{Z}_4$. While analytically only a change in sign occurs in $jz^{m\prime}$, physically a phase shifter must be placed in the equivalent circuit. Its role is to rotate the current and the voltage by 90 degrees in the same direction.

In writing, for instance, the voltage equation for mesh b_s the actual voltage drop across z_m is from left to right $-(i^{fs}-ji^{bs})z_m$. Shifting this voltage to the other side of the phase-shifter into the mesh of b_s, it now becomes $(-j)[-(i^{fs}jz_m+i^{bs}z_m)]=i^{fs}jz_m+i^{bs}z_m$. This is in the same form as given by the second equation.

On the a-c board it is not necessary to use an actual phase-shifter. The use of two generators and their cut-and-try adjustment is sufficient. The cut-and-try adjustment of the generators may be avoided by the use of open-circuit and short-circuit measurements.

The Cross-Field Equivalent Circuits

The equivalent circuit along the cross-field is found by simply transforming the equations of the revolving-field network

back to the cross-field axes with the aid of the inverse of C_3 of equation 22, namely with

$$C_z = C_z^{-1} \begin{array}{c|cc|} & s & r \\ \hline s & C_s^{-1} & \\ r & & C_r^{-1} \\ \hline \end{array} \quad C_z^{-1} = \frac{1}{\sqrt{2}} \begin{array}{c|cc|} & d & q \\ \hline f & 1 & j \\ b & 1 & -j \\ \hline \end{array} \tag{30}$$

By $C_u^* Z_4 C_b$, the resultant Z_5 is

$$Z_5 = \begin{array}{c|c|c|c|c|} & d_s & q_s & d_r & q_r \\ \hline d_s & Z_{ds}' + z_m' & -z_m' & jX_{md} & \\ q_s & -z_m' & Z_{qs}' + z_m' & & jX_{mq} \\ \hline d_r & jX_{md} & & \frac{r_r}{1-v^2} + jX_{dr} & \frac{jvr_r}{1-v^2} \\ q_r & & jX_{mq} & -\frac{jvr_r}{1-v^2} & \frac{r_r}{1-v^2} + jX_{qr} \\ \hline \end{array} \tag{31}$$

The torque tensor G_5 and impressed voltage vector e_5 have already been given as G_3 and e_3 in equations 13 and 14. The corresponding equivalent circuit and torque formula is given in Figure 6(A). It should be noted that the currents in the equivalent circuit are the same as those in the equivalent machine itself. The phase-shifter occurs in the rotor

$$i_5 = \begin{array}{|c|c|c|c|} d_s & q_s & d_r & q_r \\ \hline i^{ds} & i^{qs} & i^{dr} & i^{qr} \\ \hline \end{array}$$

Figure 10 (right). Equivalent circuit of the shaded-pole motor including space harmonics (cross-field theory)

SHIFTING PHASE-SHIFTER TO STATOR

The rotor meshes in the network may be brought to more familiar form if along the quadrature axes ji^{qs} and ji^{qr}, are introduced as variables in place of i^{qs} and i^{qr} by

$$C_4 = \begin{array}{c|c|c|c|c|} & d_s & q_s & d_r & q_r \\ \hline d_s & 1 & & & \\ q_s & & -j & & \\ d_r & & & 1 & \\ q_r & & & & -j \\ \hline \end{array} \tag{32}$$

Then $C_4^* Z_5 C_4$ multiplies each q column by $-j$ and each q row by j, giving

$$Z_6 = \begin{array}{c|c|c|c|c|} & d_s & q_s & d_r & q_r \\ \hline d_s & Z_{ds}' + z_m' & jz_m' & jX_{md} & \\ q_s & -jz_m' & Z_{qs}' + z_m' & & jX_{mq} \\ \hline d_r & jX_{md} & & \frac{r_r}{1-v^2} + jX_{dr} & \frac{vr_r}{1-v^2} \\ q_r & & jX_{mq} & \frac{vr_r}{1-v^2} & \frac{r_r}{1-v^2} + jX_{qr} \\ \hline \end{array} \tag{33}$$

$$i_6 = \begin{array}{|c|c|c|c|} d_s & q_s & d_r & q_r \\ \hline i^{ds} & ji^{qs} & i^{dr} & ji^{qr} \\ \hline \end{array} \tag{34}$$

$$e_6 = \begin{array}{|c|c|c|c|} d_s & q_s & d_r & q_r \\ \hline e_{ds} & je_{qs} & & \\ \hline \end{array} \tag{35}$$

Now the phase-shifter is in the stator as shown in Figure 6(B). This form of the network is better adapted for the introduction of space harmonics.

Part III. Space-Harmonic Equivalent Circuits

SPACE-HARMONICS OF THE STATOR

Each stator current (i^m and i^s) produces a series of fluxes with P, $3P$, $5P$, $7P$, ... and so forth, pairs of poles. Each of these fluxes cuts the rotor producing in it a current-density and flux-density wave having the same number of pairs of poles as the stator flux producing them. Hence each shaded-pole motor may be looked upon as consisting of several motors with different number of pairs of poles whose stator windings are connected in series (Figure 7).

For each motor an equivalent circuit may be developed using either the cross-field or the revolving-field reference frames. For each harmonic:

1. The rotor resistance r_r and leakage reactances x_r differ by the factor k_n

$$k_n = \frac{k_{(n)}^2}{k_{(1)}^2}$$

where $k_{(n)}$ is the nth harmonic pitch-factor.

2. The mutual impedances X_{md} and X_q, differ by k_n and also by $1/P^2$.

3. The stator leakage-impedances (functions of the angle of shift α) differ by unspecified amounts that depend on the particular design.

4. The rotor speeds v differ by P.

In order to be able to connect the stator windings of the equivalent circuits in series, it is necessary to rearrange the circuits of Figure 5 and 6 in two successive steps.

Figure 11. Equivalent circuit of the shaded-pole motor including space harmonics (revolving-field theory)

A. In Figure 8(B) the configuration of the coils of Figure 5 is changed (Figure 6 is left unchanged).

B. In Figure 9 some of the stator meshes of both networks are isolated from the rotor meshes by the use of ideal transformers.

Now the stator circuits are ready to be connected in series as shown in Figures 10 and 11. The resultant networks give the fundamental and harmonic rotor currents and torques as shown. It should be especially noted that no quantity in the harmonic meshes depends on the angle of shift α. The latter influences only the stator resistances and the leakage reactances.

Solution of the Network

The network Figure 11 of the cross-field theory is better adaptable for numerical calculation. In particular:

1. All quadrature axis meshes of the rotor may be eliminated in succession by a simple mesh-star transformation.

2. In the remaining network each transformer may be replaced by a single mutual coil.

3. All direct axis meshes of the rotor may be eliminated in succession by simply replacing two parallel impedances by a single impedance.

With the above simple steps the harmonic network has been reduced to two meshes only.

An approximate but quick method of solution consists of using the fundamental networks of Figures 5 or six to solve for the stator currents. Knowing the stator currents, the harmonic networks of Figures 10 and 11 may be solved easily for each rotor current.

Resistance Wire Strain Gauges as Elements of the Wheatstone Bridge

VINCENT J. PETRUCELLY
ASSOCIATE AIEE

ALMOST invariably, in the use of the resistance wire strain gauge, the instrument engineer employs the gauge as an element of the Wheatstone Bridge.[1-7] To use the gauge to maximum advantage, the engineer should be able to determine beforehand the behavior of the bridge circuit.

This usually requires the use of rather lengthy and unwieldy bridge equations. Further, most of the desired material is scattered throughout the literature, and is not easily available. It is the purpose of this paper to derive and assemble various characteristics of the Wheatstone Bridge, such as the output equations, condition for maximum sensitivity, and so forth, and present them in simplified form for direct application to wire strain gauges.

Consider the Wheatstone Bridge shown in Table IA.

R_1, R_2, R_3, R_4 are four arms of the bridge in ohms.

R_g is the resistance of the galvanometer detector in ohms.

V is the input voltage in volts, with polarity as shown. This source is assumed to have zero resistance.

I_g is the galvanometer or output current, in amperes.

At balance, I_g is zero. The balanced condition is

$$\frac{R_1}{R_2}=\frac{R_3}{R_4} \tag{1}$$

For an unbalanced condition, the solution for the output current can be obtained by the application of Thevenin's theorem, as follows:

Referring to Table IA, the resistance between the points cd, with R_g disconnected and the source V short-circuited, is

$$R_{cd}=\frac{R_1R_2}{R_1+R_2}+\frac{R_3R_4}{R_3+R_4} \tag{2}$$

The open-circuit voltage at cd, when the short circuit is removed from V, is E_{cd}

$$E_{cd}+I_3R_4-I_1R_2=0$$

$$E_{cd}=V\left[\frac{R_2}{R_1+R_2}-\frac{R_4}{R_3+R_4}\right] \tag{3}$$

Therefore, by Thevenin's Theorem

$$I_g=\frac{E_{cd}}{R_{cd}+R_g}=\frac{V\left[\frac{R_2}{R_1+R_2}-\frac{R_4}{R_3+R_4}\right]}{\frac{R_1R_2}{R_1+R_2}+\frac{R_3R_4}{R_3+R_4}+R_g}$$

$$I_g=\frac{V(R_2R_3-R_1R_4)}{R_1R_2R_3+R_1R_2R_4+R_1R_3R_4+R_2R_3R_4+R_g(R_3+R_4)(R_1+R_2)} \tag{4}$$

Equation 4 may be simplified as follows: (Refer to Table IA.)

Let $R_1=R_2=R_3=R_4=R$. Let the branch containing R_2 change in resistance by $\pm\Delta R$. Then the output current I_g becomes

$$I_g=\frac{V(\pm\Delta R)}{4R^2\pm3R\Delta R+2R_g(2R\pm\Delta R)}$$

$\pm\Delta R$ may be neglected in the denominator

$$I_g=\frac{V(\pm\Delta R)}{4R^2+4RR_g} \tag{5}$$

The strain acting on a strain gauge is expressed in terms of the resistance R of the gauge, the change in resistance R caused by the strain, and the wire gauge factor K_w, as follows

$$\epsilon=\frac{\Delta R/R}{K_w} \tag{6}$$

where

R = resistance of the strain gauge in ohms

ϵ = strain in inches per inch

ΔR = change in resistance of R in ohms, due to ϵ

K_w = wire gauge factor, usually supplied by the gauge manufacturer

Equation 6, when substituted in equation 5, yields

$$I_g=\frac{V\epsilon K_w}{4(R+R_g)} \tag{7}$$

from which it can be shown if more than one gauge of the same bridge circuit is active, that

$$I_g=\frac{V\epsilon K_w n}{4(R+R_g)} \tag{8}$$

where n represents the number of active gauges.

Often R_1 and R_2 are two strain gauges, only one of which is active, and R_3 and R_4 are fixed resistances, in which case[9] I_g may be found as follows:

Let $R_1=R_2=R$. Let $R_3=R_4=R_0$ = fixed resistances. Let R_2 change in resistance by $\pm\Delta R$. (Refer to Table IA.) Then

$$I_g=\frac{V(\pm\Delta R)}{2R^2\pm2R\Delta R+R_0(2R\pm\Delta R)+2R_g(2R\pm\Delta R)}$$

$\pm\Delta R$ may be neglected in the denominator

$$I_g=\frac{V(\pm\Delta R)}{2R(R+R_0+2R_g)}$$

from which it can be shown that

$$I_g=\frac{V\epsilon K_w n}{2(R+R_0+2R_g)}$$

where n is either one or two, depending upon whether one or both gauges are active.

Optimum Galvanometer Resistance

The best galvanometer resistance for maximum power in the galvanometer,

Paper 50-118, recommended by the AIEE Instruments and Measurements Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE North Eastern District Meeting, Providence, R. I., April 26–28, 1950. Manuscript submitted June 1, 1948; made available for printing February 27, 1950.

VINCENT J. PETRUCELLY, is with the American Machine and Foundry Company, Brooklyn, N. Y.

Table I

Circuit	Bridge Elements	Output	Remarks
A 	$R_1=R_2=R_3=R_4=R$	$I_g=\frac{V_eK_wn}{4(R+R_g)}$	$\epsilon=\frac{\Delta R/R}{K_w}$ n = number of active gauges K_w = gauge factor
	$R_1=R_3=R$ $R_2=R_4=R_0$ R_0 = fixed resistance	$I_g=\frac{V_eK_wn}{2(R+R_0+2R_g)}$	Same as above
B 	$R_1=R_2=R_3=R_4=R$ or $R_1=R_4=R$ and $R_2=R_4=R_0$	$E_{cd}=\frac{V_eK_wn}{4}$	Same as above c-d feeds into infinite impedance detector

for a given bridge arrangement, is given in equation 2. This satisfies the condition that the load be equal to the source impedance.

Often it will not be possible to match the galvanometer to the bridge circuit for maximum power transfer. However, the resistance of the galvanometer can differ from the resistance of the external circuit by a ratio of 6 to 1 with a loss of only 30 per cent. This can be demonstrated as follows:

If the galvanometer coil does not change in size or position with changes in the number of turns, and if the galvanometers to be compared are alike in all other respects, then it can be shown[10] that the deflection of a galvanometer is proportional to the current and the square root of its resistance, as shown below

$$\delta_g=K_1I_g\sqrt{R_g}$$

The galvanometer current is

$$I_g=\frac{V_eK_w}{4(R+R_g)}=\frac{K_2}{R+R_g}$$

therefore

$$\delta_G=\frac{K_1K_2}{R+R_g}\sqrt{R_g}$$

The greatest deflection is obtained when $R=R_g$

$$\delta_{g1}=\frac{K_1K_2}{R+R}\sqrt{R}=\frac{K_0\sqrt{R}}{2R}=\frac{0.5K_0}{\sqrt{R}}$$

For $R_g=6R$

$$\delta_{g2}=\frac{0.35K_0}{\sqrt{R}}$$

$$\delta_{g1}-\delta_{g2}=0.149K_0/\sqrt{R}$$

As a per cent

$$\text{Per cent}=\frac{0.149}{0.5}\times100$$

which is a 30 per cent loss in deflection.

The Galvanometer Current

A knowledge of the direction of the output current for tensile or compressive stresses in the arms of the Wheatstone Bridge is essential when using strain gauges in pairs. For instance, once the polarity of the output current is known under various conditions, it is possible to place gauges in the bridge so that compensation for temperature variation may be obtained, or so that the gauges will respond to axial strain and not bending strain, and so forth. As an example, assume that R_1 is in compression and that R_2 is in tension, also that $R_1=R_3=R_2=R_4$. If R_1 is in compression then it assumes some value $R-\Delta R$ and R_2 becomes $R+\Delta R$. For $R-\Delta R$

$$I_g=\frac{V(R\,\Delta R)}{4R^3-3R^2+4R^2R_g-2RR_g\,\Delta R}$$

which by inspection is positive.

For $R+\Delta R$

$$I_g=\frac{V((R+\Delta R)R-R^2)}{3R^2(R+\Delta R)+R^2+R_g(2R)(R+R+\Delta R)}$$

which also is positive.

Thus it can be seen, that for the condition where R_1 is in compression and R_2 in tension, the currents are additive. It follows that if both resistors should be in tension or compression at the same instant, their net effect on the detector would be zero, which is the condition obtained when the resistors change with temperature.

Infinite Impedance Detector

When the bridge is used with an infinite impedance detector, such as a vacuum-tube amplifier, only the open circuit voltage is of interest. This is E_{cd} as obtained in Table IB.

$$E_{cd}=V\left(\frac{R_3}{R_1+R_3}-\frac{R_4}{R_2+R_4}\right)$$

This, too, can be simplified for strain gauge work.

Let R_2 change by $\pm\Delta R$. Let $R_1=R_3=R_3=R_4=R$.

$$E_{cd}=\frac{V(\pm\Delta R)}{4R\pm2\Delta R}$$

Neglecting ΔR in denominator

$$E_{cd}=\frac{V(\pm\Delta R)}{4R}=\frac{V_eK_w}{4}$$

in general

$$E_{cd}=\frac{V_eK_wn}{4}$$

J. Avins[11] shows that the greatest sensitivity is obtained when $R_1=R_2$ and $R_3=R_4$, but the upper and lower arms need not equal each other as for the case where the detector draws current.

Usually when a vacuum-tube amplifier is used as a detector, the source of the voltage V is alternating at audio frequency, in which case the above quantities are vector quantities.[12] With alternating current the bridge is no longer phase sensitive. However, this can be overcome by operating the bridge slightly off-balance and utilizing a bridge rectifier arrangement in the output to detect a shift towards or away from balance, or by using a double balanced bridge, or ring demodulator, in which the carrier serves as a polarizing medium by virtue of its relation to the modulated carrier. The use of the ring circuit introduces other desirable features, such as operation of the bridge at zero balance, instead of off-balance, and reduction of noise, because it is double-balanced.[13,14]

For convenience, the circuits discussed are presented in Table 1.

Variable Speed Drive, Constant Frequency Alternator

G. G. GOULD
MEMBER AIEE

E. KRUPOTICH
ASSOCIATE AIEE

A CLUTCH-DRIVEN alternator, which will maintain its output frequency constant within 1 per cent although the input driving speed varies more than 80 per cent, has been developed at the Naval Ordnance Laboratory. This development resulted from the need for a source of constant-frequency alternating current in ordnance equipment wherein adequate mechanical power is available for driving a generator but where a constant speed driving source is not available, similar to conditions encountered when generators are driven from aircraft or automotive engines. Two different methods are employed to convert the variable drive shaft speed to a constant alternator speed; one is by means of a centrifugal friction slip clutch, the other by means of a centrifugally-governed magnetic-fluid clutch. The units are completely self-contained, requiring no external excitation or reference frequency and are capable of limited frequency adjustment. Their chief limitation is the loss of power in the clutches as heat, this loss being dependent on the range of driver speed variations to be accommodated.

Clutch Principles

One method of converting variable shaft speed to constant shaft speed is by means of the centrifugal friction slip clutch illustrated in Figure 1. Driving torque is transmitted to the generator through the friction coupling of six spring-loaded friction shoes slipping on a revolving driver drum. When the driver drum is rotated at the regulating speed, the difference between spring forces and the centrifugal forces due to the shoe holders is just sufficient to produce the torque required to drive the alternator. If the speed of the driver drum is increased above regulating speed, the friction shoes will slip on the driver drum maintaining constant alternator speed. In normal operation, there is always relative slip between the driver drum and friction shoes in order to accommodate both increases and decreases in driving speed. The regulating speed is set by preadjusting the spring forces.

The second method of obtaining constant speed from a variable speed shaft is by means of the magnetic-fluid clutch illustrated in Figure 2. In this clutch, a mixture of fine iron powder and oil fills the space between the two relatively moving ferrous drums. This magnetic fluid is made more or less viscous by a controllable magnetic field, whose excitation is obtained directly from the alternator through a small, full-wave dry disk rectifier. To insure alternator starting, even with no clutch exciting current, a small permanent magnet is mounted on the clutch output shaft to provide the requisite starting torque and to permit excitation build-up as in ordinary d-c generators. A later model employs a centrifugal switch instead of the permanent magnet for starting. Automatic frequency control is obtained by regulating the amount of clutch current by use of a Lee type centrifugal governor in the clutch circuit. At a predetermined speed, depending on the governor setting, the governor contacts tend to open due to centrifugal force; however, since this tends to reduce the control current and in turn the governor speed, the generator maintains constant speed for any further drive speed increase. The regulating speed is chosen by preadjustment of a small backing screw on the governor so as to accommodate both normal increases and decreases in driving speed.

Figure 3 shows a complete, self-contained clutch-driven alternator having an output of 200 watts at 200 cycles. Either a centrifugal-friction clutch or a magnetic-fluid clutch is incorporated in the housing.

Frequency Regulation

The alternator output frequency varies slightly with slip speed as shown in Figure 4. Slip speed, which is defined as the difference between the driver and regulating speeds, is plotted as per cent of the regulating speed, while the frequency variation is plotted as the per cent change from the frequency at 30 per cent slip speed. For the friction clutch, the change in output frequency is due to the change in the coefficient of sliding friction with slip speed. For the magnetic-fluid clutch, the output frequency is independent of slip speed, except at high values of slip where heating alters the magnetic-fluid viscosity. Even with this slip effect it is seen that at constant electric load the alternator frequency remains constant within 1 per cent for large changes in driver speed.

Changes in alternator load have a more pronounced effect on frequency than changes in slip speed. Figure 5 shows the effect of change of load on the friction clutch, where a change in load from full load to no load caused the frequency to rise 1.2 per cent. The magnetic-fluid clutch is not as sensitive to load changes as the friction clutch; the frequency remains within one half per cent for all load changes.

The frequency versus time trace for a typical 1-hour run is shown in Figure 6, where the drive speed is varied every ten minutes and frequency continuously re-

Paper 50-119, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE North Eastern District Meeting, Providence, R. I., April 26–28, 1950. Manuscript submitted November 4, 1949; made available for printing March 24, 1950.

Figure 1. Centrifugal friction slip clutch, disassembled

Figure 3. Self-contained clutch-driven constant frequency alternator

corded. Although the frequency for both clutches remained constant within 1 per cent, the friction clutch shows its characteristically slow frequency decrease with time due to wear of the friction material and of heating, while the magnetic-fluid clutch shows failure to regulate above 100 per cent slip speed due to centrifugal packing of the iron powder.

Excellent response to transient speeds is characteristic of both types of clutches. There is neither hunting nor overshooting during the transient period even though the driver speed is rapidly varied. The alternator frequency responds to the drive speed change, but remains constant within one half per cent. Similarly, the "warm-up" time from a cold start is of short duration; the generator frequency is up to 1 per cent of steady frequency as fast as the prime mover can come up to speed.

Limitations

Since the clutches must accommodate both decrease as well as increase in driving speed, there will always be slip between driver and driven members. Consequently, power is continuously dissipated in the clutch as heat, the amount of such power being equal to the ratio of slip speed to regulating speed times the power output. This limits the size of generator that can be driven by the clutches. For the two clutches shown, the temperature rise is about 40 degrees centigrade above ambient at full load.

In the friction clutch, wear of the friction shoes requires their replacement after about 20 hours of running. Although the proper choice of friction shoe and driver drum materials will help minimize the wear encountered, it is not possible to eliminate wear entirely. The manifestation of wear is the gradual decrease in regulating frequency of approximately 1 per cent after five hours of running.

The magnetic-fluid clutch is not troubled with wear, but it does require periodic maintenance because of loss of oil from the iron-oil mixture. Due to centrifuging, the iron tends to separate from the oil; while due to heat, the oil is driven out of the clutch. Thus, the clutch characteristics are slowly changed in time. Although adequate life tests have not been performed, it appears that this clutch can be operated for at least 20 hours without requiring servicing.

Considerably longer service-free life can be obtained readily with both types of clutches by increasing clutch sizes. The units built are intended for short life, intermittent duty, and hence are small physically.

Design Factors

The alternator is of conventional design, incorporating a permanent magnet rotor and a wound stator, with the number of poles chosen to permit the highest possible drive speed in keeping with the strength of the Alnico rotor and the desired frequency. Since high centrifugal forces yield improved speed regulation for the friction clutch, and, furthermore, since high speeds yield smaller generator size, the clutch was designed to regulate at 6,000 rpm, and driven at 6,500 to 12,000 rpm. The magnetic-fluid clutch, however, was designed to regulate at the lower speed of 4,000 rpm and driven at 4,200 to 8,000 rpm because of separation of iron from oil due to centrifugal forces. This decreased regulating speed reduced the maximum generator output by one third.

Changes in drive speed, load, and temperature affect the coefficient of sliding friction in the friction clutch. Even for constant speed and constant shoe pressure, the friction force available for driving the generator will vary with time when the clutch is brought up to speed from a cold start. For good speed regulation it is necessary to choose a combination of friction shoe material and driver drum material which exhibits the least change in friction due to temperature, pressure, or slip speed. By experimental means, it was determined that the best clutch operation was obtained by using a copper-base, sintered friction shoe material, of the type commonly used for clutch or brake applications, mating against a chromium-plated steel drum.

Figure 2. Magnetic-fluid clutch parts and generator housing

Figure 4 (left). Change in alternator frequency as drive speed is changed at constant full load

Figure 5 (right). Change in alternator frequency as load is changed at constant drive speed

This combination of materials yields a high coefficient of sliding friction which is relatively constant, and further does not result in excessive wear of either the shoe or the drum.

As noted previously, centrifuging and sealing are the primary problems encountered with the magnetic-fluid clutch. The separation of iron powder from the oil can be minimized by judicious design and by the use of the correct quantity of magnetic-fluid based on the design. As to sealing, standard type shaft seals have been found to be satisfactory for retaining the iron particles; nevertheless, the oil does gradually disappear from the magnetic fluid.

Frequency Setting

By use of a calibrated spring scale, each of the six compression springs of the friction clutch is set accurately to a specified loading, thereby ensuring that all friction shoes take an equal load. Tests have shown that it is possible to preset the regulating frequency of the generator within an accuracy of two per cent. To effect minor changes in frequency, each of the six adjusting screws is rotated by an equal amount, thereby slightly increasing or decreasing the force of each spring by an equal amount.

Figure 6. Frequency variation with time, as drive speed is changed every ten minutes

For the magnetic-fluid clutch, frequency setting is readily accomplished by merely adjusting the governor spring backing screw. With the centrifugal governor used, it is possible to set the regulating frequency to any value between 150 and 220 cycles per second.

Applications

The clutches and associated control systems described are suitable for many applications where a constant output speed is desired from a source of variable speed power. The simplicity of control and the excellent transient response of the clutches commend their application in fractional horsepower equipment, provided the losses due to clutch heating can be tolerated. In addition to the use of the clutches as frequency regulating devices, they have been successfully used as accurate voltage regulating devices on d-c generators driven from variable speed shafts.

Other applications that have been suggested, especially for aircraft or for automotive use, are as constant speed drives for pumps and fans.

Discussion

P. H. Trickey (Vickers Electric Division, Vickers Inc., St. Louis, Mo.) Mr. Gould and Mr. Krupotich are to be commended for their development of a constant frequency drive from a variable speed source. It may be of interest to know that the magnetic fluid clutch which they have used in a small size for short life, has now been developed successfully by Vickers Incorporated for use on much larger sizes, and for normal life of thousands of hours.

G. G. Gould and **E. Krupotich:** Mr. Trickey's comments are appreciated, especially since he is well cognizant of the many detailed problems which had to be solved to produce a successful clutch. It is gratifying to note that the magnetic fluid clutch has been applied successfully to larger units than the ones developed at the Naval Ordnance Laboratory, as this justifies the confidence placed on the system for speed regulation. The short, service-free life of the units developed does not necessarily indicate unsatisfactory characteristics. The clutches were specifically designed for maximum load at the expense of longer life, and further required to accommodate unusually large driver speed variations. The service-free life of both types of clutches can be extended appreciably by increasing the size of the units or, even for the same size, by decreasing the slip speed.

Failures of Rubber Insulation Caused by Soil Microorganisms

JOHN T. BLAKE
ASSOCIATE AIEE

DONALD W. KITCHIN
NONMEMBER AIEE

ORISON S. PRATT
NONMEMBER AIEE

AN earlier paper[1] reported the investigation of the cause of the rare failures of nonleaded rubber-insulated cables buried directly in the ground. These failures were characterized by localized regions of very low insulation resistance. The absorbed water content was no greater than in adjacent regions of high insulation resistance, and the physical properties were usually normal. Drying the failed insulation raised the resistance several decades, but brief exposure to moisture restored the low values. It was suspected that these failures had been caused by the action of soil microorganisms.

A study was made in the laboratory with conditions favoring microbial activity. By exposing thin walls of insulation to soil of high microbe content, adjusted to neutral or slightly alkaline pH, and kept moist and warm, it was possible to accelerate the action so that failures like those occasionally found after ten or more years under actual service conditions were produced in a few weeks. Parallel tests in active soil, sterilized soil, and water showed conclusively that the drastic loss of insulation resistance in active soil was due neither to water absorption nor to the action of soil chemicals, but to attack by living microorganisms.

In the actual operation of underground cables the most favorable combination of conditions necessary for producing failure by microbial attack occur only rarely.

Since certain soil microbes can consume the natural rubber hydrocarbon, failure of natural rubber insulation is usually accompanied by visible surface pitting. Synthetic rubber insulation shows no visible signs of attack even after a six decade drop in resistance. This suggests some fundamental difference between the mechanisms of microbial attack on natural rubber and synthetic rubber insulation.

The present paper is concerned principally with these mechanisms and with the composition and structure that tend to make rubber insulation vulnerable to such attack. Experimental evidence is given to show that the *GR-S* and butyl hydrocarbons are not consumed by soil microorganisms, and that the invisible faults leading to electrical failure occur only where microbes eat out other materials present in the synthetic insulating compound.

Methods of Locating Faults

To study the faults in rubber produced by microorganisms it is necessary to locate them precisely. Searching along a failed wire sample with a test probe is neither sensitive nor precise enough. Several methods of locating such faults are described below.

Use of Electrolyte with a Color Indicator

A simple method of locating faults is to immerse the failed sample in an electrolyte containing phenolphthalein. The conductor is made negative to the bath. Voltages from 100 to 500 volts may be used. At any faults sufficiently leaky the development of alkali produces a red color. Figure 1 shows a failed sample on which 65 color spots could be counted. This method does not mark the faults permanently nor reveal their nature directly.

D-C Corona Test

A more sensitive and rapid method is to stress a wet failed wire sample with about 5,000 volts (conductor negative) under reduced air pressure. Figure 2 shows a sample with five corona spots. Another sample showed over 20 such spots. The resistance of a single typical fault is of the order of 10 megohms, whereas that of the surrounding intact region is usually of the order of 10,000,000 megohms per foot of sample. Thus the leaky spots act like point electrodes to produce stress concentrations which break down the air near them. Considerably higher voltage is required to produce corona over-all, so that the effect is clean-cut. Alternating stress would be much less effective because the capacitive current through the whole insulation would mask the leakage current through the faults.

Electrodeposition of Copper in Faults

Some faults produced by microbes in rubber insulation can be located and permanently marked by immersing failed wire samples in a copper sulfate solution and making the conductor 100 to 500 volts negative to the solution. After a period of several days surface specks of metallic copper appear at some of the faults. If the treatment is continued these specks grow to copper nodules, while new small specks may appear, Figure 3. In a number of samples insulated with laboratory-mixed stock certain faulty regions showed hundreds of fine copper specks after this treatment, Figures 4 and 5.

When the insulation was sliced off to various depths, particles could be found all the way through the wall. These were too minute to be seen by unaided eye, but their color made them visible at a

Paper 50-121, recommended by the AIEE Insulated Conductors Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE North Eastern District Meeting, Providence, R. I., April 26–28, 1950. Manuscript submitted January 27, 1950; made available for printing March 22, 1950.

JOHN T. BLAKE, DONALD W. KITCHIN, and ORISON S. PRATT are all with the Simplex Wire and Cable Company, Cambridge, Mass.

Figure 1. Locating faults with color indicator

magnification of 100 X. To obtain good photographs it was necessary to intensify the specks in the cut layers by additional plating, Figure 6.

Of these three methods of locating faults the electrodeposition of copper on failed samples has shown the most about the nature and distribution of faults. As a quick routine means of counting faults the d-c corona is more convenient.

Since the first copper ions have to traverse the wall of insulation before they are deposited, the copper filament grows from the conductor outwards. It is extremely fine. After it reaches the surface further deposition leads only to nodule formation without thickening the filament inside the pore. The copper-bearing channels are not always radial, but sometimes run in many directions, a fact which suggests the existence in the insulation, before microbial attack, of paths more vulnerable than the surrounding insulation.

In the copper-treated faults no continuous, solid filaments have been found that would cause a short circuit. Instead the pores contained practically single-file aggregates of microscopic copper particles. It was not possible by dissolving the rubber away to leave any continuous copper filaments since they were too fragile.

Figure 2. Locating faults with d-c corona

In the previous paper the presence of invisible faults in *GR-S* insulations that had failed was demonstrated, but the structure of these faults was not established. Two alternatives were suggested, namely that these faults were either: regions of insulation degraded by diffused microbial products until the rubber there had extremely low resistivity; or actual holes through the insulation. The results of the copper deposition test show that the faults are holes.

Evolution of Hydrogen in Faults

Some failed samples did not show copper specks even though the measured microampere-hours passed through the insulation in the copper sulfate solution were equivalent to an appreciable deposit. If copper were present, but merely too finely distributed to be seen, it could be recovered by electrodeposition on a platinum wire and weighed. Careful experiments failed to detect any copper in these samples. The leakage current had been carried by ions other than copper ions. Hydrogen ions seemed the most likely carriers. To test this a sample which had failed to show deposited copper after several days in the copper sulfate bath was placed in the same electrolyte in a glass tube where the hydrogen was collected and measured. After a week a few copper specks appeared, but about 90 per cent of the current through the sample was accounted for by the evolved hydrogen.

Microorganisms could hardly produce a pore with a diameter smaller than that of a copper ion. It is more probable that hydrogen gas evolved at the conductor forms bubbles in the pores that markedly reduce the leakage current. One failed sample showed a four-decade rise in resistance during a prolonged electrolytic test. Soaking in hot water without voltage allowed the hydrogen to diffuse out and restored the initial low resistance.

Two Types of Microbial Attack

When wire samples which have failed in the accelerated laboratory soil exposure test are inspected the most obvious difference is that the surface of the natural rubber insulation is usually badly pitted, that of the *GR-S* rubber insulation not at all. This suggests a fundamental difference between the modes of attack on the two types of rubber.

Figure 3. Locating faults with electrodeposited copper

The severe microbial pitting so far found in natural rubber insulation, but not in the synthetics, is the more obvious action, Figure 7. Its progress can be noted visually long before there is any decrease in insulation resistance. Dielectric strength tests would be expected to show impending failure, but to produce drastic loss of sample resistance the microbes have to eat all the way through to the conductor. The breach in the insulation may eventually become a rather coarse hole rather than a micropore, since there is no reason for the microbes to prefer a radial direction when they can consume the insulation in bulk. It has been shown[1-7] that a number of soil microorganisms can readily consume natural rubber either as the pure rubber hydrocarbon or as a part of a vulcanized compound. Unless a natural rubber insulation is protected by adequate preventives, the microbes can eventually eat through the wall. This type of attack appears to be little affected by differences in physical texture imparted by variations in processing.

The mechanism of the microbial attack which creates micropores is more obscure. This occurs in both natural and synthetic rubber insulation. In natural rubber the microporous regions are much less numerous than the pitted regions, yet the samples fail through the micropores long before any pits reach the conductor. Figures 4 and 7 illustrate this point. They show two regions of a sample of natural

Figure 4. Electrodeposited copper showing micropores in natural rubber insulation

Figure 5. Electrodeposited copper showing micropores in GR-S insulation

rubber insulation which had failed in the accelerated laboratory soil test. The electrodeposited copper in Figure 4 shows the presence of many pores that traverse the wall all the way to the conductor. Before the copper treatment this spot showed no visible signs of attack. This was the only microporous region observed. On the other hand, there were very many pitted regions like those shown in Figure 7. Although these regions had been exposed to exactly the same conditions no copper specks were found in these pits nor signs of leakage by any other tests. The wall of insulation under the pits appears to have remained sound. To cause failure by pitting the microbes have to consume the bulk insulation all the way to the conductor. This is a process which seems to be much slower than the one which creates the micropores.

Figure 6 shows the same microporous region as Figure 4 after 70 per cent of the wall had been sliced off and the copper filament ends, visible only under the microscope at 100 X, had been intensified by additional copper plating.

Since microbial attack on *GR-S* insulation does not create pits, visual examination does not show whether it has failed or not. Failure is detected by loss of insulation resistance. To locate the faults one of the tests described above is required. Figure 8 shows samples of failed *GR-S* insulation after copper deposition. Although these samples had suffered a loss of resistance of six decades or more the surface remained smooth and shiny. The existence of the micropores is revealed by the electrodeposited copper.

In *GR-S* insulation that failed the absence of surface erosion, the random direction of the pores, and their minute size imply that the insulation is not uniformly vulnerable, but that even before exposure to soil microorganisms, it contains "imperfections" in otherwise inert material. These are minute veins of microbe food scattered in a random manner throughout a medium that microbes cannot consume. This microbe food is neither water-soluble nor hygroscopic, since control samples in water maintain normal resistance indefinitely. Soil microbes eat out the insoluble food and leave in its place some hygroscopic material. This makes the resistance of the pores very low when the sample is wet, but very high when it has been allowed to dry.

Evidence of the Existence of Imperfections

There is a variety of evidence for the existence of these imperfections. If the bulk insulation could be consumed by soil microorganisms, we should expect, after prolonged soil exposure and failure, to find both severe surface erosion and much larger pores. There would also be no reason for the peculiar orientation and the zigzag course of the pores so often observed when samples are examined after copper deposition. The electrical evidence relating to these imperfections is especially interesting. Considerable light is thrown on the probable structure both by the trend of insulation resistance versus soil exposure when the test is continued several months after initial failure, and by the d-c breakdown values on samples not exposed to soil but simply soaked in hot water.

Figure 9 shows the peculiar trend of resistance of *GR-S* insulation when exposure to soil is continued after failure. These accelerated laboratory soil exposure tests were made on ten samples of number 14 solid wire with a 3/64-inch wall of a *GR-S* compound having low water absorption. The samples were consecutive 5-foot lengths from the same length of wire run in the factory. Ten samples in soil all failed in ten months or less. Four control samples in water maintained normal resistance.

The course of the attack is presumably as follows. Some soil microorganisms, not yet identified, consume food in the minute streaks. Until the first micropore reaches the conductor the effect on the sample resistance is negligible. As soon as the pore passes all the way through the wall, the resistance drops several decades. After this first drop the decrease

Figure 6. Section of insulation shown in Figure 4 with copper deposits in micropores intensified by further plating

Figure 7. Characteristic pitting of natural rubber

is very gradual. As more pores traverse the wall they decrease the resistance relatively little. For example, ten faults having equal leakage lower the sample resistance only one decade more than a single fault. If a pore kept increasing in diameter because the microbes could consume the surrounding medium the sample would soon be practically short circuited. This levelling off of the sample resistance after the first sharp decrease, together with the extreme minuteness of the pores and the absence of any visible surface erosion seem to be convincing proof of the correctness of the postulated structure of the imperfections.

There is other independent evidence. Visual tests described later in this paper show that the *GR-S* hydrocarbon does not support microbe growth, but that raw *GR-S* contains materials that do. These materials and others added in the compounding are believed to be the food in the imperfections.

Effect of Processing on Stability of GR-S Insulation in Soil and On D-C Breakdown after Hot Water Soak

Whether a given rubber insulating compound is processed in the factory or in the laboratory the regular physical and electrical tests usually show no significant difference in quality. In the soil exposure tests, if the insulation is not inherently resistant, or made so by the addition of effective preventives, wire samples made in the laboratory have almost invariably proved to be more vulnerable than those made in the factory. Thus the structure, as influenced by the processing, that is, the thoroughness and uniformity of mixing, is an important factor in determining the stability in soil.

One of the most effective means of testing rubber insulation for structural imperfections not revealed by low resistance is to make d-c breakdown measurements on samples which have been soaked several days in hot water. If fissures, micropores, or poorly bonded interfaces extend only partly through the wall their effect on the insulation resist-

Figure 8. Copper deposits on *GR-S* sample. (Note absence of erosion)

ance may be negligible. Direct voltage stress causes breakdown at the weakest spot. It is a local, not a bulk effect. After a few days soaking in water at 158 degrees Fahrenheit an imperfection in only a fraction of the wall thickness can lower the d-c breakdown considerably. Water which diffuses to an imperfection acts like a sharp electrode to produce high local stress concentration and breakdown.

In the following experiment, *GR-S* insulation having abnormal vulnerability to soil microbes also showed low d-c breakdown strength. Samples were prepared of number 14 solid wire with 3/64-inch wall of *GR-S* insulation having low water absorption. The formulation was identical in all samples, but the processing in the three groups was thus:

1. Insulation processed entirely in the factory.
2. Insulation mixed in the factory, extruded and vulcanized in the laboratory.
3. Insulation processed entirely in the laboratory.

The usual tests for insulation resistance versus soil exposure were made on samples from each group. Table I shows the initial megohms and the megohms after four months in soil (five feet buried length). Another set of samples from the same groups was soaked three days in water at 158 degrees Fahrenheit and then broken down by d-c stress.

Control samples for the soil tests showed no drop in insulation resistance in water. Samples from each group, after being dried two days at 185 degrees Fahrenheit showed an average value of 2,300 volts per mil apparently not significantly affected by the variations in processing. Thus the major physical factor affecting both stability in soil and d-c breakdown strength is the completeness of mixing. Although the low d-c breakdown voltages and the rapid failure in soil may not both be caused by the same imperfections, it is evident that the kind of mixing that produces the highest d-c breakdown after hot soak also increases the stability in active soil. It is not surprising that the factory mixing should prove superior.

The difference with regard to stability in soil is one of degree only. The results in Figure 9 and those in the third column of Table I were obtained with samples from the same length of factory-run wire. The better mixing thus merely delayed failure. These were only 5-foot lengths, yet in one sample the d-c corona test revealed 20 micropore faults. It seems unlikely that any amount of mere physical processing would guarantee unlimited stability in service lengths of thousands of feet, which a few microbe faults might put out of operation. On the other hand, certain types of *GR-S* insulation made inherently resistant by the addition of effective microbe preventives have been stable in soil even when the processing is not thorough enough to produce optimum d-c breakdown strength after hot water soaking. The d-c breakdown strength after hot water soaking is thus an index of structural integrity, regardless of inherent resistance to microbe growth. The visual fungus test described later shows whether the material is inherently resistant to microbe attack without regard to the thoroughness of mixing. These two tests are entirely independent.

The ideal insulation is one combining maximum resistance to microbe growth with the best possible physical structure.

Protection of Insulation by Jackets—Staggered Imperfections

Tough neoprene jackets are commonly used over the insulation of nonleaded

Table I. Effect of Processing on Stability and Breakdown

Laboratory Mixed and Insulated	Factory Mixed Laboratory Insulated	Factory Mixed and Insulated
Initial Megohms in Soil		
2,700,000	2,100,000	2,500,000
2,700,000	2,200,000	3,000,000
2,700,000	2,300,000	3,100,000
2,900,000	2,200,000	3,500,000
Megohms after 4 Months in Soil		
400	3,300,000	2,000,000
8	2,900,000	2,100,000
3	3,100,000	2,300,000
4	700	2,400,000
Volts Per Mil D-C Breakdown after 3 Days in Water at 158°F		
750	1,000	1,100
750	1,200	1,200
700	1,100	1,300
700	1,200	1,200

Figure 9. Dielectric resistance versus time of exposure to soil

underground cables to provide mechanical protection and weather resistance. It is desirable that they should also protect the insulation against attack by soil microorganisms. It is not satisfactory to test the resistance of neoprene jacket compounds to microbial attack by extruding them directly on a copper conductor and measuring insulation resistance versus soil exposure. The resistivity of such compounds is inherently low, and this tends to mask the effect of failures produced by microorganisms.

The most significant laboratory test is carried out by coating wire with insulation known to be susceptible to microbes, applying a layer of neoprene compound over this, burying the samples in soil, and making periodic megohm measurements between conductor and soil. The resistance of the jacket is so low that it does not interfere with the measurement.

Since two different mechanisms of attack had been observed in the failures of natural rubber and *GR-S* insulation, it was of interest to test the effect of neoprene jackets over both types. Ten five-foot samples of number 14 solid wire with 3/64-inch wall of a natural rubber insulation and a 25-mil wall of neoprene jacket compound were buried in soil and four were immersed in water. Those in water showed normal high resistance during 13 months. All ten soil test samples failed in 9 to 13 months with an average drop in insulation resistance of three decades. This is less than that observed when the insulation is directly exposed to soil. Even an imperfect jacket delays the attack and restricts it to a small fraction of the total area. These failures indicate that the microbes traverse the neoprene jacket, presumably through food streaks or imperfections. When they reach the natural rubber at any point they can cause failure by consuming the bulk insulation.

In a parallel test ten samples with similar jackets but with *GR-S* insulation

showed no decrease in resistance during 15 months in soil. Four control samples in water also maintained normal resistance. Two samples of the same *GR-S* insulation without jackets showed normal resistance for ten months but drops of four to six decades after 13 months.

The marked difference in relative stability of the *GR-S* and the natural rubber insulation under neoprene jackets of identical type is most easily explained by applying the imperfection theory to the case of two layers. Since microbes cannot consume the bulk material of either neoprene or *GR-S* they have to find imperfections in both to cause failure. Even when these are numerous the probability of an imperfection in the jacket registering exactly with one in the insulation is small. If this does happen the sample should eventually fail. In general the imperfections would be expected to be staggered in such a way that failures in jacketed *GR-S* samples would be rare.

In another experiment to test this idea a 2-layer *GR-S* insulation is being compared for stability in soil with a single layer of the same thickness.

The statement in the earlier paper that neoprene compounds appear to be inherently resistant to soil exposure is true only in the sense that like *GR-S* they do not show visible results of microbe attack. If a neoprene jacket contains food streaks microbes can eat through it and attack susceptible natural rubber under it.

In a preliminary experiment samples of wire insulated with a 15-mil wall of vulcanized latex covered with a 20-mil wall of a neoprene jacket compound were exposed to soil until they had failed. The jacket was stripped from short pieces and these were quickly placed on sterile nutrient agar. In a few days white colonies starting from the wire spread gradually over the agar surface. The microorganism was identified as a species of Fusarium.

Experiments of this type are valuable both to show that microbes can traverse the jacket and also to identify those that do.

Figure 10. Visual fungus test on raw *GR-S* with additives

Figure 11. Fungus on raw *GR-S*

Accelerated Visual Test of Microbial Attack

The decisive laboratory test of the stability of underground cable insulation is the periodic measurement of insulation resistance of samples buried in soil for long periods under conditions most favorable to microbial attack. In this test susceptible samples fail in a few months. As compounds more resistant to soil exposure are developed the time to failure may become excessively long. A means of quickly showing whether a compound is inherently resistant to soil microbes is of great advantage.

A simple visual test provides such a means. Small pieces of material, which may be either vulcanized insulation or raw rubber or other polymer are placed on a thin layer of soil sprinkled over moist sand. The test may be accelerated by dusting the sample lightly with dried soil. The amount of material for such a test is very small and much processing time is saved.

Most susceptible materials show considerable fungus growth in a week or two. For example, the *GR-S* insulation on the samples of Figure 9, some of which took ten months to fail electrically, showed profuse fungus growth in about two weeks on the visual test. This test shows whether the insulating compound is inherently resistant and is independent of the degree of mixing.

One use of this visual test is illustrated in Figure 10. The samples are pieces of raw *GR-S 65* with various additives. At the left is a blank containing no additives. All samples had equal milling. Figure 11 shows an unmilled lump of *GR-S* after several weeks in a closed bottle over inoculated water. Without other tests the profuse growth of fungus on the raw *GR-S* could be misleading. When the same type of *GR-S* has been acetone extracted it shows no fungus growth after many months on this test. Even if the *GR-S* is badly oxidized after extraction by prolonged heating, it does not support growth. The *GR-S* hydrocarbon is not a source of microbe food. When the acetone extract is evaporated on aluminum foil and exposed to soil, heavy fungus growth appears, Figure 12. The immunity of purified *GR-S* supports the imperfection theory of failure of *GR-S* insulation. It accounts for the absence of surface erosion.

Growth of fungus on a particular insulation in the visual test does not prove that failure in soil of that insulation was directly caused by fungus. The fungus serves as an indicator which shows whether the compound is attractive to microorganisms in general. In doubtful cases the visual test may not be a sufficient criterion. On the other hand, an insulation that supports profuse fungus growth would be a poor risk for underground cable insulation. A large number of unpromising materials can be screened out with little effort. To-date the routine soil exposure tests on rubber insulation have confirmed the predictions of the visual test.

A practical application of this test is illustrated in Figures 13 and 14. Both samples have similar *GR-S* insulation of low water absorption, but with different combinations and amounts of preventives. Compound *A* showed visible fungus growth in one week. Compound *B* showed no growth during nine months test. Thus the implication of the visual test was that compound *A* would be unstable in soil, *B* stable.

To check this, 5-foot lengths of number 14 solid wire with 3/64-inch wall of insulation were prepared. Four samples of each type were buried in active soil, four in sterilized soil, and four immersed in

Figure 12. Fungus on acetone extract of raw *GR-S*

Figure 13. Visual fungus test on GR-S compound A

water. In water and in sterilized soil all samples have maintained normal resistance for a year. In active soil all four samples of compound *A*, which showed fungus in the visual test in one week, failed after three to five months. The four samples insulated with compound *B*, which showed no growth on the visual test, have maintained normal high resistance for one year. These results confirmed the predictions of the visual test for these particular compounds.

A similar confirmation was obtained with the natural rubber samples jacketed with a particular neoprene compound. The jacket showed profuse fungus growth on the visual test. The corresponding ten samples failed in the accelerated soil exposure test.

Visual fungus tests on individual materials aid in the choice of compounding ingredients. It is not safe, however, to use these results to predict the stability of complete insulating compounds. For example, although raw neoprene, both as received and after extraction with alcohol, shows no fungus growth in this test, a typical neoprene jacket compound may support profuse growth within a week. Certain insulating compounds may show no growth in the unvulcanized condition, but abundant fungus after vulcanization. The interaction of compounding ingredients during vulcanization may change susceptibility to microorganisms. The only safe test is one made on the final insulation. If a compound shows no appreciable fungus growth, the visual test should be followed up by making periodic measurements of insulation resistance on wire samples buried in soil.

Pure natural rubber hydrocarbon supports growth of microorganisms. In the visual test the first growth seems to be Actinomycetes appearing wherever the sample contacts the soil. This is followed by fungus growth. Raw butyl rubber generally shows little or no fungus growth. A slight growth of an organism cultured and identified as a species of Tricoderma was observed on some samples, but acetone extracted butyl rubber shows no growth at all. Butyl rubber severely oxidized after acetone extraction also fails to show growth of fungus. Paraffin wax and Heliozone show excessive growth. A high paraffin content tends generally to make compounds more susceptible to microbial attack. In neoprene compounds the effect of paraffin is peculiar. It blooms rapidly to the surface where it supports heavy fungus growth. A number of preventives that are effective in insulating compounds do not inhibit such growth on neoprene compounds, presumably because they are not sufficiently soluble in the paraffin layer. They also may reach the surface more slowly than the paraffin. If the microorganisms merely ate off the paraffin film without further action, this would not be cause for concern. It is not safe to rest on that assumption. This is shown by the failure of the samples jacketed with neoprene compounds that showed fungus growth in the visual test.

Summary

The failure of rubber insulation brought about by soil microorganisms can best be detected by a decrease of several decades in the insulation resistance. To study the mechanism of attack and the physical structure that makes rubber insulation vulnerable to such attack it is necessary to have means of locating and marking the failed spots. Several methods of doing this have been described. The electrodeposition of copper in the micropores created by microbes affords the most insight into the physical structure of the faults. Two distinct modes of attack have been shown. The simpler one which is characteristic of natural rubber, is a progressive eating away of the bulk insulation. The second more obscure type creates micropores through the wall, but without any visible surface erosion. This mode is typical of the synthetics in which the base hydrocarbon or polymer, if freed of extraneous microbe food, does not support microbe growth. The imperfections consist of streaks of microbe food scattered in a random manner through otherwise inert material. Their distribution is affected by physical processing. These streaks are not hygroscopic and do not lead to failure in prolonged immersion in either hot or cold water. They do, however, tend to lower the d-c breakdown of samples after several days soaking in hot water. Thus with a given susceptible compound it is possible to predict which processing will produce the greatest stability in soil by breakdown tests on samples not exposed to soil. The breakdown tests relate to physical structure. To test the inherent resistance of a material to soil exposure the simple visual fungus test is very convenient. The validity of this test as a criterion of stability has so far been confirmed by the routine resistance tests after accelerated laboratory soil exposure. It is not safe to predict the stability of a complete compound from the results of visual tests on the base material. The vulcanized insulation must be tested. Insulating compounds shown to be promising by the visual test should be given a thorough soil exposure test.

The testing of preventives is a field in itself. It is not simple. Materials which are strongly antiseptic in water may not be so when mixed in a rubber compound. Many of them would be completely unsuitable in rubber insulation. Some preventives are effective in a compound before it is vulcanized but not afterwards. Some are completely inactivated by certain other necessary or desirable ingredients. Others may leach out in time and cease to protect the material. Oxidation inactivates some preventives. A nicely balanced compound is required to produce insulation with sufficient stability in soil, proper physical characteristics, and high electrical quality.

Discussion

F. E. Kulman (Consolidated Edison Company of N. Y., Inc., New York, N. Y.): This paper presents evidence that rubber insulations fail by microbiological deterioration and describes a mechanism by which the materials are damaged. Rubber compounds in which the base polymer may or may not be inert to microorganisms contain imperfections, scattered in a random manner throughout the medium, which are nutrient to microorganisms. When the food particles are consumed the damage appears as micropores which can be located and marked by the deposition of copper in them. The concept of the formation of micropores, as described by the authors, represents an advance in our knowledge of the limitations of cable materials and provides the opportunity of producing better cable insulations and jackets. Since raw neoprene which is used so widely as a jacket base in network cables is apparently immune to microorganisms, improvements in these cables can be expected.

Since the spring of 1948, the microbiological services of a research laboratory have been engaged by the Consolidated Edison Company of New York to investigate the bacterial corrosion of metals and the microbiological deterioration of nonmetallic protective coatings and jackets which are applied to underground feeder pipes and lead sheaths for corrosion prevention.

Samplings of the soils in New York City have shown the presence of five types of bacteria which may influence metal corrosion and at least 23 species of fungi and actinomyces which may cause coating deterioration. Quantities of the soil have been removed to the laboratory and short sections of coated pipes and cables placed therein. Similar specimens of pipes and cables were placed in steam-sterilized soil as controls. Periodic measurements of insulation resistance are being made to determine whether the materials are deteriorating. Preliminary results showed severe deterioration of cellulose or cellulose derived coatings.

Visual tests of nutrient inertness, conducted in accordance with Joint Army-Navy specifications, were found to be useful in screening out inferior coating materials. The visual tests are made in glass jars at 28 degrees centigrade and 95 to 98 per cent relative humidity with the spores of four prescribed types of aggressive fungi sprayed on the test materials. These tests can be made in as short a period as two to four weeks.

To assure long life of underground pipes and cables it is most desirable to select a coating material which is nutriently inert to microbiological damage. Insufficient work has been done on incorporating fungicides in coating or jacketing materials which are not inherently inert. The results of our tests to date have shown that the coatings being used on the pipes containing high voltage feeders or carrying high pressure gas in New York are inherently inert. Microbiological tests should be required on the new synthetic materials before they are accepted for widespread underground use as jackets or coatings.

The authors of this paper have made a significant contribution to electrical engineering and it is hoped that the investigational work which they have done so capably can be continued to completion.

Kenneth S. Wyatt (Phelps Dodge Copper Products Corporation, New York, N. Y.): The authors have opened up a new field of study in electrical insulation. They have devised ingenious techniques for detecting the attacks of microorganisms and for observing their mechanisms. The paper is stimulating because it is a bright example of what can be done by able investigators by carefully conceived methods thoroughly executed.

Microbial attack of cable insulation appears widespread in the tropics. When in Caracas, Venezuela, three years ago, and on subsequent trips, I was puzzled by the failure of long lengths of 5-kv rubber cable in the foothills after only a year or two of service. The same thing happened at Mercedes several hundred miles southeast. The bitumenized Hessian finish on cable standing in the yard for six months or less would crumble to powder in the fingers. This and other considerations led me to the conclusion that the trouble was due to bacteria. I now began to look for these troubles as I travelled about. I found they were highly localized. Conditions of humidity, temperature, and pH value have to be just right. My limited observations indicated little or no trouble on the islands of Aruba or Curacao, which are volcanic with a surrounding coral formation. There is some trouble in Puerto Rico and Jamaica, and I believe Maracaibo is bad. I am considering not only microbial attack of buried cable but fungus attack of aerial cable.

Knowing what microbial attack looks like, one begins to observe cable troubles due to this cause in our own country in subtropical areas, such as Florida and the Gulf Coast. I have seen control cable troubles further north in power stations where temperature humidity (moist ducts) and pH were favorable.

As to materials, rubber was most vulnerable, although neoprene was reported attacked. Vinylite cannot be used because the plasticizer evaporates off in the hot tropical sun. Polyethylene was resistant to airborne fungi in Jamaica, and is believed resistant to soil bacteria.

For these tropical areas it begins to be clear that cable should be especially designed. It is useless to ship out jute coverings. Rubber must have special attention and protection. But we have to guard against not only soil bacteria and aerial fungi, but also against white ants and termites which will corrode through steel tapes and then drill the insulation; flying beetles which bore holes in the lead sheath; in lakes and rivers, teredos which riddle rubber, neoprene and vinylite; and greatly accelerated corrosion because of the high temperature. A rubber-insulated cable, shielded for the higher voltages but without cotton tapes, protected against borers by a soft untinned bronze tape quarter-lapped, and protected against bacteria and fungi (and against corrosion) by a continuous pigmented polyethylene sheath, would appear to answer the tropical cable problem.

In investigating susceptibility of insulating materials to soil bacteria and aerial fungi, there are pitfalls into which many have stumbled. The methods employed by the authors appear to me to have great merit.

Robert J. Wiseman (The Okonite Company, Passaic, N. J.): The authors of this interesting paper have added another item to the list of possible causes of failure of rubber-insulated cables, thereby removing another item from "cause unknown." We all have observed occasionally a failure of a rubber cable, and could not assign a cause after making check tests on the voltage breakdown of an adjacent sample, power factor tests and physical tests. We are indebted to the authors for reporting on their findings, yet we must be careful in drawing conclusions. We are in the early stages of this approach to the operation and life of rubber insulation and, therefore, must not be hasty in believing that because microorganisms attack some rubber insulations, we must abandon its use. We all know there are many millions of feet of rubber insulated cables in duct and directly buried which are giving excellent service. In a majority of cases we can determine the cause of a failure. If we could reivew past failures on the basis of attack by microorganisms, I venture to state that the percentage will be extremely small and, therefore, let us not get excited about it. Rather let us take advantage of this approach and try to learn more about its mechanism, such as: what kind of organisms attack rubber or rubber-like material? What are the kinds of so-called food that they like? Can we geographically determine where the attack is most likely to occur? We know during World War II that the South Pacific area was a nightmare to all kinds of materials due to bacteria action. Are warm localities more subject to attack than cooler climates? What is the effect of partially moist soil, that is, not bone dry and not water saturated? What is the degree of alkalinity necessary to get the greatest effect? Why,

according to the authors, do we get a pitting action on the surface of rubber insulation made with natural rubber and not with synthetic rubber? Apparently, it is not the pitting that will cause a failure, but the micropores that exist for both natural and synthetic rubbers. Therefore, neither is better than the other in resisting attack. The authors report that *GR-S* raw rubber showed attack, but after it was treated with acetone it showed a very high degree of resistance and the extract did show the microorganism could attack it. Does this mean it is necessary to treat all raw *GR-S* with acetone before usage? Imagine the cost! What effect does prior treatment on raw rubber have on its resistance to attack? Some cable manufacturers do not bother to wash the raw rubber before compounding. We, at Okonite do, as we consider it essential to obtain a uniform product. Perhaps we unconsciously have been carrying out some of the requirements for good resistance to microorganisms.

The authors suggest considerations be given to adding something—we will call it "*X*" to a rubber compound to overcome the effect of bacteria. Let us go slowly on this. As soon as the composition of a rubber compound is changed, its physical and electrical characteristics also are liable to change. So we can be worse off than what we are trying to correct. This effect cannot be evaluated in the laboratory under accelerated conditions, but must be watched in the field under operating conditions which takes years before reliable conclusions can be drawn.

The authors infer that because of their findings, natural rubber should be abandoned for synthetic rubber, because both natural and synthetic rubber showed micropores to occur and it is the latter that causes failure, principally, as I understand it, because they found pitting of the surface of natural rubber compounds. I am not in accord with their viewpoint. It is based on too little and doubtful evidence. Furthermore, it must be recognized that many years of excellent service experience with properly manufactured natural rubber insulated cables irrefutably testify to their worth, whereas cables made with synthetic rubber are only a few years old; in fact, actually since World War II because *GR-S* made during the war was far from a suitable material. The constant changing by some manufacturers of the composition of their synthetic rubber compounds before any worthwhile field experience has been obtained is puzzling. Years ago we went through these growing pains with natural rubber compounds. Some of us fared better than others. Today we furnish a long life, natural rubber insulation which can be subjected to all the variables that cables are prone to and it is known where we stand. I do not feel that this is true for synthetic rubber insulation. It appears that each year a new composition is proposed so that we are constantly in a state of hope or wishful thinking that we have a satisfactory rubber insulation.

Let us continue the study reported by the authors and we are indebted to them for reporting it to us, but it also is important that we do not draw hasty conclusions that we will regret later.

J. T. Blake, D. W. Kitchin, and **O. S. Pratt:** The experiments and findings described in the discussions of F. E. Kulman and K. S. Wyatt are valuable contributions to the general problem of protection against underground hazards. In this and our earlier paper[1] the study was confined to microbial attack on rubber and rubber-like materials. The extremely interesting description by Mr. Wyatt of the other hazards met in the tropics and the methods of overcoming them covers another aspect of the problem.

Dr. Wiseman's discussion presents several interesting points of view. We are in hearty agreement with some of these but not with others. In neither of our papers is there any recommendation that rubber be abandoned for underground use. Dr. Wiseman stresses the fact that failures from microbe attack in service have been very rare. In both papers, particularly in the earlier one, we emphasized strongly their infrequency and explained it.

Some of the questions asked by Dr. Wiseman about the effect of different environmental conditions are covered earlier in the paper. We have shown that failure of even such vulnerable insulation as thin natural rubber vulcanized latex was absent or greatly retarded in dry, flooded, or cold soil. Partially moist, fertile, neutral, or slightly alkaline soil is the most active in causing failure. The question about the likelihood of failure in various geographic regions is very well covered in Mr. Wyatt's interesting discussion.

The questions: "What kind of organisms attack rubber or rubber-like materials? What kinds of so-called food do they like?" are at least partially answered in our two papers. We found, as did several earlier investigators, that natural rubber can be consumed in bulk by certain bacteria, actinomycetes, or fungi. We have not observed so far any direct consumption of acetone extracted raw *GR-S* or butyl rubber, or of raw neoprene by any of the foregoing microorganisms. The so-called foods are the acetone soluble soaps, fatty acids, paraffin, and other waxes.

The question of why there is pitting on natural rubber insulation but not on synthetic rubber insulation, we believe to be explained in the section on the two types of microbial attack. The microbes can consume bulk natural rubber but not *GR-S* or butyl rubber. The experiment with acetone extracted raw *GR-S* demonstrated this fact. No suggestion was made that *GR-S* be acetone extracted for cable usage.

Dr. Wiseman's deduction that, because failure in a particular natural rubber sample occurred sooner by micropores than by pitting, neither natural nor synthetic rubber is better in resisting attack, is one with which we cannot agree in the light of our experimental results. There is no reason to suppose that the slower process of direct consumption of natural rubber is somehow arrested before failure.

A striking and practical illustration of the difference between natural rubber and *GR-S* insulation is given by the results on neoprene-jacketed wire samples of identical construction except that one set had natural rubber insulation, the other *GR-S* insulation.

The tests are described in the section on jacket protection and staggered imperfections. As stated, all ten natural rubber samples failed in soil in nine to 13 months. In the corresponding *GR-S* set the two unjacketed controls failed in 11 months and now are down five decades (21 months). Of the ten jacketed samples in soil nine are still normal at 21 months. Only one started to drop at 16 months, and this levelled off at three decades down where it has remained for the last four months. This is attributed to geometric protection which one would expect on statistical grounds. It is a fact that the minute vulnerable food streaks in the insulation and in the jacket coincide extremely seldom. With uniformly vulnerable natural rubber this geometric or statistical protection is completely absent. Since the *GR-S* samples had no added preventive and those without jacket failed drastically, it seems reasonable to ascribe the observed protection to the geometry.

Dr. Wiseman's warning to go slowly on the addition of preventives is quite in line with the final paragraph of our summary, except for his objection to accelerated laboratory tests. The development of inherently resistant compounds would be greatly retarded if we had to wait 15 to 20 years each time a new compound or preventive was tried.

Similar arguments could be advanced pro and con for all other accelerated laboratory tests. Very few research or development laboratories would consent to abandon such tests or give up a valuable tool in their constant striving to develop improved rubber insulating compounds.

Series-Connected Saturable Reactor with Control Source of Comparatively Low Impedance

H. F. STORM
MEMBER AIEE

Synopsis: The object of this analysis is to shed light onto the mechanics of magnetic-amplifier operation and to derive simple, and yet reasonably accurate, formulas. The analysis deals with the effects of various parameters, such as voltage, frequency, load resistance, and feedback. The various mathematical expressions are condensed into a nondimensional, normalized master graph which completely describes the steady-state operation of the magnetic amplifier under consideration. Speed of response and its relation to the gain are also investigated. The formulas and conclusions are verified by test data.

ONE FORM of magnetic amplifier uses saturable reactors whose load windings are connected in series. Besides other variables, operation of the magnetic amplifier is influenced by the relative magnitude of currents induced into the control windings from the load windings. These induced currents become larger as the outer control-circuit impedance decreases and therefore are largest when the outer control-circuit impedance is zero; conversely, for very high outer control-circuit impedance, the induced currents become practically zero. Consequently, the series-connected saturable reactor may be divided into one category where the outer control-circuit impedance is comparatively small (with respect to the referred load resistance), and another where the outer control-circuit impedance is relatively high. While the latter category has been analyzed in another paper of the author,[1] the following analysis deals with the case where the control-circuit impedance is very small. Such reactors are widely used in industry, for instance, in theater-lighting controls, speed controls, and voltage regulators.[2,3,4]

A rigorous analysis of saturable-reactor circuits becomes quite difficult due to the presence of nonlinear and multivalued functions. The following analysis relinquishes some rigor in return for a quicker and clearer understanding of the fundamentals. In addition, it permits the performance to be calculated simply and yet with a reasonable degree of accuracy. To this end, simplifications are made so that good agreement is obtained between theoretical calculations and actual test results. It should be kept in mind, however, that simplifications, by their very nature, result in solutions which are accurate only as long as the simplifications closely approximate real conditions. This reservation should be kept in mind when interpreting the results of this paper.

One approximation consists in reducing the hysteresis loop to a single-valued function; this is often permissible, if, as in our case, the core losses of the reactor are not considered. The wide present-day use of grain-oriented steels and other square-loop materials permits a further simplification since the magnetization characteristic can be represented by three straight lines,[5] Figure 1(A). If the magnetic intensities in the core of the saturable reactor are much larger than H_s (see Appendix for definitions of symbols), a further simplification is possible by reducing H_s to zero, resulting in the rectangular characteristic of Figure 1(B): this approximation becomes increasingly accurate with core materials of high differential permeabilities (50,000 gauss per oersted or more), as previously mentioned. Leakage reactance of the load windings is considered negligible in comparison with the load resistance. The resistance of the load windings, the feed-back windings, and the feed-back rectifier is included in the load resistance R_L, and the resistance of the control windings is lumped into the control-circuit resistance R_C. By premise, the control-circuit resistance R_C' is small with respect to the load resistance R_L, when referred to the same side of the saturable reactor.[6] The reverse current of the feed-back rectifier is to be assumed zero.

The magnetic amplifier described in the following consists of two magnetic circuits (Figure 2) arranged in such a manner that voltages of fundamental frequency and odd harmonics are cancelling each other in the control circuit.[7] The two magnetic circuits may consist of two separate units, A and B as shown, or they may be embodied in a 3- or 4-legged construction without change of basic performance. Each of the two units exhibits the essentials of a single-phase transformer: an iron core, one winding, $X1$-$X2$, connected as load winding; a second winding, $Y1$-$Y2$, used as control winding; and a third winding, $Z1$-$Z2$, used as feed-back winding. The load current i_L flows through load winding $X1$-$X2$ of unit A, from there through part of the rectifier, and into an ammeter which reads the average value I_L; then, depending upon the position of switch S, the current either flows directly through the remaining part of the rectifier, or if switch S connects points 7 and 8, the load current will flow first through the feed-back windings, $Z1$-$Z2$, of the two units A and B before emerging from the rectifier. From here the current flows through the load winding, $X1$-$X2$ of unit B, and into the load resistance R_L. Increasing the control voltage E_C will strengthen the

Paper 50-123, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Great Lakes District Meeting, Jackson, Mich., May 11-12, 1950. Manuscript submitted February 9, 1950; made available for printing March 20, 1950.

H. F. STORM is with the General Electric Company, Schenectady, N. Y.

control current I_C and result in a larger load current I_L. As will be shown later, control current and load current are proportional over a wide range and, therefore, this circuit is suitable for measurement purposes; within limits, this proportionality, which is a fundamental feature of saturable reactors, is obtained despite variations of line voltage, frequency, and load resistance.

The dots in Figure 2 signify winding polarities. A current is called positive when it flows through the winding in a direction away from the dot. The magnetomotive force F is called positive when derived from a positive current, and the positive direction is indicated by arrows F_A and F_B. The voltage across the winding is defined as positive when the terminal with the dot is more positive than the other terminal. The a-c supply voltage e is counted positive when the a-c bus with the dot is the more positive.

Voltage, Flux, and Current Wave Shapes

Let switch S be in the position shown in Figure 2 and consider the magnetic amplifier to be in steady-state operation. As will become clearer shortly, there is good reason to assume that at $\theta=0$ the flux ϕ_A in core A equals Φ_1 and the flux Φ_B in core B equals the saturation flux Φ_s, the operating point at this instant being right at the knee of the magnetization line, Figure 1(B). The line voltage e will cause a magnetizing current to flow through the load windings $X1$-$X2$ of units A and B. With a rectangular magnetization line, this current will be very small (theoretically zero) and, hence, its voltage drop in the load resistor is negligible. The voltage of point 4, therefore, is practically identical with the voltage of bus 5. Thus the line voltage is applied to the two units A and B in series, and because of the identity between units A and B, one-half of the line voltage will appear across $X1$-$X2$ of unit A and the other half across $X1$-$X2$ of unit B, Figure 3(D).

As a result of the application of the voltage $e/2$, a flux change $\phi_{\Delta,A}$ will now occur in core A

$$\frac{e}{2}=\frac{d\phi_{\Delta,A}}{dt}N_L10^{-8} \tag{1}$$

Figure 1 (left). (A). Magnetization line represented by three straight lines. (B). Rectangular magnetization line

Figure 2 (below). Elementary circuit diagram of magnetic amplifier

Figure 3 (right). Theoretical wave shapes of voltage, flux, and current

Figure 4. Oscillogram showing the wave shapes of line voltage e, load current i_L, control current i_C, and voltage $e_{L,A}$ across load winding of unit A

The line voltage

$$e = E_m \sin \theta \tag{2}$$

where

$$\theta = \omega t = 2\pi f t \tag{3}$$

Integrating equation 1 and substituting from equation 2 one obtains

$$\phi_{\Delta,A} = \frac{1}{2}\frac{10^8}{\omega N_L} E_m \int_0^\theta \sin\theta \, d\theta$$

$$= \frac{1}{2}\frac{10^8}{\omega N_L} E_m (1 - \cos\theta) \tag{4}$$

The core flux ϕ_A is

$$\phi_A = \Phi_1 + \phi_{\Delta,A} \tag{5}$$

Because the load winding of unit B is connected into the same circuit with opposite polarity, the application of the remaining half of the line voltage will cause a flux swing in core B which also has the opposite sign

$$\phi_{\Delta,B} = -\phi_{\Delta,A} \tag{6}$$

And the flux ϕ_B in core B becomes

$$\phi_B = \Phi_2 - \phi_{\Delta,A} \tag{7}$$

Figure 3(E) shows how flux ϕ_A increases while ϕ_B decreases at the same rate. Finally for $\theta = \alpha$, core A becomes saturated, and hence can no longer produce a voltage across its terminals $X1$-$X2$. This is also true for the control winding ($Y1$-$Y2$) of unit A which now looks almost like a short circuit as seen from the terminals $Y1$-$Y2$ of unit B. The effective impedance across terminals $X1$-$X2$ of transformer B becomes very small and the line voltage e will appear in practically full strength across the load resistance R_L. This is shown in Figure 3(D) where, at $\theta = \alpha$, the sinusoidal voltages across terminals $X1$-$X2$ of units A and B collapse and jointly reappear across R_L, Figure 3(A). The load current becomes

$$i_L = e/R_L \tag{8}$$

Because the voltage $e_{L,B}$ across the load winding of unit B is zero for $\alpha < \theta < \pi$, no further flux change (equations 1 and 6) takes place and ϕ_B remains constant. However, the core flux can remain constant only if the sum of all the magnetomotive forces acting on the core remains constant, which means that a current i_C must flow through the control winding

$$i_{L,B} N_L + i_C N_C = 0 \tag{9}$$

This is shown in Figures 3(B) and 3(C). The events during the next half-cycle are analogous. It will be seen that the control current i_C contains a d-c component I_C. This d-c component cannot be supplied by transformer action, but requires a discrete voltage source in the control circuit, $E_C = I_C R_C$. This last requirement is the closing link in the chain of events so far discussed.

The oscillogram of Figure 4 shows the close agreement between the theoretical wave shapes of Figure 3 and the actual observation.

The Law of Equal Ampere Turns (Proportional Region)

The phenomenon of equal but opposing ampere turns (equation 9) is closely related to the function of a-c transformers; however it differs from it by the fact that in the saturable reactor, this action takes place during only one half-cycle. However, there are two saturable reactors in the circuit, and while the transformer action takes place during only one half-cycle per core, this transformer action alternates between the two cores. As far as the total circuit is concerned, transformer action occurs continuously. Because of the polarities involved, the secondary current-transformer current (i_C) is unidirectional.

It follows from the numerical equality of instantaneous ampere turns that the average rectified-load ampere turns $I_L N_L$ are equal to the average control ampere turns $I_C N_C$.

$$I_C N_C = I_L N_L \tag{10}$$

This is an important fundamental characteristic of saturable-reactor circuits. The region in which this equality occurs is called the proportional region. As previously pointed out, the assumption of a rectangular magnetization curve is valid only if the magnetic intensities in the core are large by comparison with H_s.

Figure 5. Master graph

Figure 6. Load current I_L as function of control current I_C. Solid lines are calculated, dots are measured points

Therefore equation 10 and its ramifications should not be applied to the vicinity of $I_L N_L = 0$; for instance, for zero control ampere turns, the load current cannot become zero because this would require an infinite reactance, which cannot be realized.

Resistance-Limited Region

It will also become evident that a continuous increase of control current cannot produce an unlimited increase of load current. As shown later, an increase in control current I_C causes an increase of Φ_1 in the positive direction. When $\Phi_1 = \Phi_s$ each saturable reactor is saturated over π radians, which means that the total impedance of both load windings in series theoretically becomes zero. At this point (and for larger control currents), the load current reaches its maximum value $I_{L,m}$, which is limited by the load resistance R_L only:

$$I_{L,m} = E/R_L \tag{11}$$

This region is called the resistance-limited region. Voltage E is the rectified average value of the line voltage with the crest value E_m.

$$E = \frac{2}{\pi} E_m \tag{12}$$

Actually, maximum current is a little smaller because of air-core reactance.

Master Graph

Figure 5 shows the results of the theory (full lines), and the experimental results (indicated by dots). As previously mentioned, the section OA is called the proportional region (equation 10) and section AC is called resistance-limited region (equation 11). In order to make the graph general, both sides of equation 10 are divided by $N_L E/R_L$. The representation then becomes nondimensional and such graph is also called normalized. In keeping with the terminology applied to electric machinery, the ratio $I_L/I_{L,m}$ is called the per-unit load current, and the ratio $m_{1,2} I_C N_C/(I_{L,m} N_L)$ the per unit ampere turns, where m_1 or m_2 as defined later, and equal to unity for the case of no feedback. Then the relation between per unit ampere turns and per unit load current becomes a straight line, which for identical scales, subtends an angle of 45 degrees with the axes.

A reversal in the polarity of the control voltage E_C will produce a symmetrical characteristic $OA'C'$. In the case without feedback ($m_1 = m_2 = 1$), the load current depends only upon the absolute value of the control current, and characteristics OAC and $OA'C'$ are axially symmetrical.

In places where the power loss in the resistance R_L becomes of interest, the effective value $I_{L,eff}$ can be expressed by the form factor k_f

$$k_f = I_{L,eff}/I_L \tag{13}$$

of which experimental values are plotted in Figure 5.

The rectified average current becomes

$$I_L = \frac{1}{\pi}\int_\alpha^\pi i_L d\theta = \frac{1}{\pi}\frac{E_m}{R_L}\int_\alpha^\pi \sin\theta\, d\theta = \frac{1}{\pi}\frac{E_m}{R_L} \times (1+\cos\alpha) \tag{14}$$

where α is the angle of retard (Figure 3). From equation 12

$$I_L = \frac{E}{2R_L}(1+\cos\alpha) \tag{15}$$

and from equation 10

$$\cos\alpha = 2\frac{I_C N_C}{I_{L,m} N_L} - 1 \tag{16}$$

The angle of retard α and its cosine are plotted on separate axes in Figure 5.

Overexcitation and Overexcited Region

The maximum flux swing $\Phi_{\Delta,m}$, Figure 3(E), is obtained from equation 4, substituting $\theta = \alpha$ from equation 16, and from equation 12

$$\Phi_{\Delta,m} = \frac{10^8}{8fN_L} E(1-\cos\alpha) = \frac{10^8}{4fN_L} \times (E - I_C R_L N_C/N_L) \tag{17}$$

When $\Phi_{\Delta,m} = 2\Phi_s$, the operation is called normal excited, for $\Phi_{\Delta,m} < 2\Phi_s$, underexcited, and for $\Phi_{\Delta,m} > 2\Phi_s$, overexcited. So far, all our considerations were based on the wave shapes obtained from Figure 3, which, by its geometry, pertains to the normal and underexcited cases only. It is the object of the following discussion to extend the range into the overexcited region.

Let us define the rectified average no-load saturation voltage $E_{s,0}$ as the line voltage which will cause a flux swing of $2\Phi_s$, for $I_C = 0$, then one obtains from equation 17

$$\Phi_{\Delta,m} = 2\Phi_s = \frac{10^8}{4fN_L} E_{s,0} \tag{18}$$

$$E_{s,0} = 8f\,\Phi_s N_L\, 10^{-8} \tag{19}$$

Figure 7. Load current I_L as function of line voltage e. Solid lines are calculated, dots are measured points

If the line voltage is raised above $E_{s,0}$ the saturable reactor may operate in a different fashion, depending on its degree of loading. Suppose $I_C=0$ and

$$E=\xi E_{s,0} \tag{20}$$

where ξ is called the per unit excitation. The flux swing $\Phi_{\Delta,m}$ cannot physically become larger than $2\Phi_s$, and therefore the reactor cannot hold a larger voltage than $E_{s,0}$ (equation 19). The balance $E-E_{s,0}$ is driving the minimum current $I_{L,\min}$ through the load resistance

$$I_{L,\min}=\frac{E-E_{s,0}}{R_L} \tag{21}$$

Increasing the control current from $I_C=0$ will not increase the load current $I_{L,\min}$ until the control current succeeds in producing a flux swing $\Phi_{\Delta,m}=2\Phi_s$ according to equation 17

$$\Phi_{\Delta,m}=\frac{10^8}{4fN_L}(E-I_CR_LN_C/N_L)=2\Phi_s$$

$$=\frac{10^8}{4fN_L}E_{s,0} \tag{22}$$

and

$$\frac{I_CN_C}{(E/R_L)N_L}=\frac{E-E_{s,0}}{E} \tag{23}$$

The control current can be increased from zero to the value of equation 23 without causing a change in the load current $I_{L,\min}$ of equation 21. This region is called the overexcited region, and its representation becomes a horizontal line $B'B$ in the normalized graph of Figure 5. The overexcited characteristic takes priority over the proportional characteristic $B'OB$.

During overexcited operation ($B'B$) the angle of retard α is constant and equals the value of α at points B and B' of the proportional region. When the control current reaches the value shown by equation 23 (points B and B'), normal excitation takes place, and for further increases of control current, underexcitation occurs. Equation 10 is therefore valid for BA and $B'A'$ only. With further increase of I_C the resistance-limited regions $C'A'$ and AC will be reached, where the load current remains constant, but where the control current undergoes changes in wave shape.

The Complete Master Graph and Its Ramifications

With the addition of the overexcited region, the effect of line voltage has been added to the normalized characteristic of Figure 5. Because $E_{s,0}$ is also a function of the line frequency (equation 19), the latter is thereby represented in the normalized graph (equation 21).

We see now that the operation of the saturable reactor is completely described by the per unit excitation ξ and the per unit ampere turns. These relations are of particular importance when model laws are to be evolved and when comparisons among different reactors are made. The normalized graph of Figure 5 embodies all circuit parameters (even feedback, to be discussed later) and therefore constitutes a master sheet from which the steady-state performance of the saturable reactor can be predicted for any set of circumstances.

Load Current Versus Control Current

Suppose the object is to predict the load current I_L as a function of the control current I_C, with line voltage, frequency, and load resistance remaining constant. The first step is to multiply the axes of Figure 5 by E/R_L. The second step is to assume scales for I_L and I_C, for instance, Y amperes per unit for I_L, and X amperes per unit for I_C. When substituted from equation 10, the slope $\tan\gamma$ of the proportional region is (Figure 6)

$$\tan\gamma=\frac{I_L/Y}{I_C/X}=m_{1,2}\frac{N_C}{N_L}\frac{X}{Y}$$

Third, a straight line OB subtending the angle γ is drawn through the origin. Fourth, intersection is made at D with a horizontal DD' at the distance $(E-E_{s,0})/R_L$, and intersection at B is made with the horizontal BC at the distance E/R_L. Thus the desired characteristic $ADBC$ has been quickly obtained. Numerically this characteristic is based on: $E=62.2$ volts, $E_{s,0}=42.8$ volts, $N_C=400$, $N_L=592$, $R_L=346$ ohms, $X=Y=0.1$ ampere per unit, $\tan\gamma=0.676$. A check by actual measurement has been made and the dots of Figure 6, representing the measured points, indicate the close agreement between calculation and observation.

Load Current Versus Line Voltage

The effect of line voltage on the load current is quite interesting. By freezing all parameters in the normalized graph except E, the load current I_L can be obtained by a geometric manipulation, which, because of its simplicity, is not further described. The practical procedure, however, is illustrated: Assume scales for I_L and E, for instance Y amperes per unit for I_L, and X volts per unit for E. The slopes of OA and CF (Figure 7) follow from

$$\tan\delta=\frac{1}{R_L}\frac{X}{Y}$$

The starting point C of CF is for $E=E_{s,0}$. A horizontal line BD is drawn at the distance $m_{1,2}I_CN_L/N_C$. The total characteristic is now $OBDF$. The line voltage can change theoretically by $E_{s,0}$ volts without causing a change in load current. This is an important feature in d-c measuring devices. The characteristic shown in Fig-

Figure 10. Oscillogram of load current I_L and control current I_C, when control voltage E_C was increased

Figure 11 (right). Oscillogram of load current I_L and control current I_C, when control voltage E_C was decreased

ure 7 is based on: $E_{s,0}=42.8$ volts; $N_C=400$; $N_L=592$; $R_L=395$ ohms; $I_C=64$ milliamperes; $X=20$ volts per unit; $Y=0.04$ ampere per unit; tan $\delta=1.266$. The dots in Figure 7 show measured points.

Load Current Versus Line Frequency

Next the effect of frequency on the load current will be demonstrated (Figure 8): Suppose the no-load saturation voltage $E_{s,0,1}$ is known for the frequency f_1, then point D on the abscissa axis has the value $Ef_1/E_{s,0,1}$. The straight line AD has a slope

$$\tan\psi=\frac{1}{R_L}\frac{E_{s,0,1}}{f_1}\frac{X}{Y}$$

with X cycles per second per unit and Y amperes per unit. Point A could alternatively be obtained from its ordinate value of E/R_L. Intersection at B is obtained by a horizontal line BC at the distance $m_{1,2}\ I_CN_C/N_L$, with $m_{1,2}\ I_CN_C/N_L$ not to exceed E/R_L. The total frequency characteristic is now ABC and it can be seen that an increase of frequency beyond point B will not change the load current. The characteristic of Figure 8 is based on: $E_{s,0,1}=42.8$ volts; $f_1=60$ cycles per second; $N_C=400$; $N_L=592$; $R_L=210$ ohms; $I_C=50$ milliamperes; $X=10$ cycles per second per unit; $Y=0.04$ ampere per unit; tan $\psi=0.849$. Again good agreement is obtained between the theoretical and measured points.

Load Current Versus Load Resistance

The effect of load resistance on the load current can also be derived from the normalized characteristic and can be conveniently plotted on log-log paper (Figure 9). The straight line $1C$ is inclined under 45 degrees with the axes. For $\xi\leq 1$ the load current is represented by the horizontal AB until intersection occurs with $1C$ at B; then, with increasing R_L, the load current declines along BC. For $\xi>1$ the load current follows another 45-degree line ED at low values of R_L. This new locus intersects the ordinate axis ($R_L/E=1$) at $1-1/\xi$ (point F); specifically for $\xi=1.25$, point F is at 0.2. Starting at low values for R_L, the load current decreases (ED) with increasing load resistance. Then the plateau DB is reached and the load current follows the pattern for $\xi\leq 1$ (DBC). We see that over a certain range, the load resistance does not affect the load current.

The theory has again been verified by measurements, and two cases are shown in Figure 9, one for $\xi=1$ and the other for $\xi=1.25$. $E_{s,0}=42.8$ volts; $f=60$ cycles per second; $N_C=400$; $N_L=592$; $I_C=60$ milliamperes. The measured points are indicated by dots for $\xi=1$ and by crosses for $\xi=1.25$. The minimum value for R_L is given by the resistance of the load windings. Good agreement between calculated and measured values has again been obtained.

Apparent Inductance

The sum of the core fluxes follows from equations 5 and 7

$$\phi_A+\phi_B=\Phi_1+\phi_{\Delta,A}+\Phi_s-\phi_{\Delta,A}=\Phi_1+\Phi_s \quad (24)$$

and is a constant quantity. Φ_1 is seen from Figure 3(B).

$$\Phi_1=\Phi_s-\Phi_{\Delta,m} \quad (25)$$

Substituting from equation 25 into equation 24

$$\phi_A+\phi_B=2\Phi_s-\Phi_{\Delta,m} \quad (26)$$

In order to express the sum of the core fluxes by the control current, substitution is made from equations 17 and 18

$$\phi_A+\phi_B=\frac{10^8}{4fN_L}(E_{s,0}-E+I_CR_LN_C/N_L) \quad (27)$$

It should be noted that this equation holds only for the proportional region, and more specifically, excluding the vicinity $I_LN_L=0$ and $m_{1,2}\ I_CN_C \geqslant I_{L,m}N_L$.

The inductance of a circuit is

$$L=\frac{d\phi}{di}N10^{-8} \quad (28)$$

For finite changes of $\Delta\phi$ and Δi the inductance becomes

$$L\doteq\frac{\Delta\phi}{\Delta i}N10^{-8} \quad (29)$$

Because of the average character of I_C, differences according to equation 29 should be introduced instead of differentials, and ΔI_C is considered averaged over 1/2 cycle. The apparent inductance of the control circuit follows from equations 27 and 29

$$L_C=\frac{\Delta(\phi_A+\phi_B)}{\Delta I_C}N_C10^{-8}=\frac{1}{4f}R_L\frac{N_C^2}{N_L^2} \quad (30)$$

One obtains the rather surprising result that the inductance of the control winding is proportional to the load resistance R_L and inversely proportional to the frequency, while the core permeability which is of paramount importance in linear reactors does not even appear in equation 30. For I_LN_L nearly zero, the actual operation of the saturable reactor is entirely different and equation 30 cannot be applied.

Time Constant

In the case of an ordinary linear inductance L connected in series with a resistor R, the sudden change in the driving voltage will cause an exponential variation of current with time, the time constant being $T=L/R$. A similar variation with time takes place in the saturable reactor as demonstrated by the oscillograms of Figure 10 for rise, and Figure 11 for fall. An exponential function plotted on semilog paper becomes a straight line. Therefore, by plotting the average value of each half-cycle of the oscillograms of Figures 10 and 11 on semilog paper, a check is obtained with respect to the exponential character of the function. This has been done in Figure 12 and one recognizes that the points for rise and fall straddle very closely a straight line. The conclusion is that the current changes in an exponential fashion, and therefore the change of load current with respect to time can be expressed by a time constant. This time constant is the same for rise and fall as proved by the single straight line of Figure 12.

In analogy to the time constant of a linear reactor, the time constant T in seconds of the saturable reactor becomes

$$T=\frac{L_C}{R_C}=\frac{R_L}{R_C}\frac{N_C^3}{N_L^2}\frac{1}{4f} \tag{31}$$

If we call R_C' the control resistance referred to the load circuit

$$R'=R_C N_L^2/N_C^3 \tag{32}$$

the time constant becomes

$$T=\frac{1}{4f}\frac{R_L}{R_C'}\text{ seconds} \tag{33}$$

One recognizes that the load resistance and control-circuit resistance affect the time constant in inverse manner: an increase in control circuit resistance speeds up the response, whereas an increase in load resistance slows down the response. The time constant is also inversely proportional to the frequency, becoming shorter with an increase of frequency. This fact can also be expressed by stating that the time constant measured in cycles depends on resistance ratio only

$$T=\frac{1}{4}\frac{R_L}{R_C'}\text{ cycles} \tag{34}$$

For the case shown in Figures 10 and 11 ($R_L=1{,}600$ ohms, $R_C=5.2$ ohms, $N_L=910$, $N_C=200$), T follows from equation 34 as 3.7 cycles; the measured value of T from Figure 12 is 3.8 cycles.

It should be pointed out that for time constants of less than one cycle, equation 34 becomes inaccurate and indicates too small values for T. Furthermore, equation 34 will yield too small results if the cores are not well saturated during part of the cycle. Such condition is encountered when the per unit load current is very small; under these circumstances the time constant may become many times larger than expressed by equation 34.

Feedback

It has been previously stated in connection with equation 9 that during the period when one core is unsaturated, the sum of all ampere turns is zero in this core. If we change the position of switch *2* in Figure 2 to make contact between points *7* and *8*, the ampere turn relation for $\alpha<\theta<\pi$ now becomes for positive i_C

$$i_{L,B}N_L+i_F N_F+i_C N_C=0 \tag{35}$$

The winding *Z1* and *Z2* are called feed-back windings and have N_F turns per winding. This case is illustrated in Figure 13.

If one assumes that the feed-back rectifier has no reverse current

$$i_F=-i_{L,B}=i_L \tag{36}$$

Hence

$$i_L(N_L-N_F)=i_C N_C \tag{37}$$

and in analogy to equation 10

$$I_L(N_L-N_F)=I_C N_C \tag{38}$$

With a positive control voltage E_C, the feed-back ampere turns are aiding the control ampere turns and hence this feed-back is called positive. It is well to recognize the very important fact that, with positive feedback, a much smaller control current is sufficient to obtain the same load current as without positive feedback.

When comparing the case with positive feedback to the case without feedback, the following relation between the control ampere turns of the two cases can be obtained from equations 10 and 38

$$(I_C N_C)_{\text{no feedback}}=(I_C N_C)_{\text{pos. feedback}}\times\frac{N_L}{N_L-N_F} \tag{39}$$

Defining

$$m_1=\frac{N_L}{N_L-N_F} \tag{40}$$

the ampere turns without feedback can be directly calculated by multiplying the ampere turns of the positive feedback case by m_1. Therefore by attaching the feed-back multiplier m_1 to the positive abscissa axis of the normalized characteristic (Figure 5), it also becomes valid for positive feedback. The case without feedback is characterized by $N_F=0$, in which case m_1 degenerates to unity.

By reversing the polarity of the control source E_C, core *A* will now be unsaturated for $\alpha<\theta<\pi$. In analogy to equation 35, we obtain

$$i_{L,A}N_L+i_F N_F+i_C N_C=0 \tag{41}$$

where

$$i_F=i_{L,A}=i_L \tag{42}$$

Hence

$$i_L(N_L+N_F)=-i_C N_C \tag{43}$$

Substituting average terms

$$I_L(N_L+N_F)=-I_C N_C \tag{44}$$

Disregarding the negative sign of $I_C N_C$, one recognizes that more control ampere turns are now needed with feed-back than without, and hence this feed-back is called negative. In analogy to the preceding, a feed-back multiplier m_2 is defined for negative feedback

$$m_2=\frac{N_L}{N_L+N_F} \tag{45}$$

By attaching the feed-back multiplier m_2 to the negative abscissa axis of the normalized characteristic (Figure 5) its range is extended into the negative feed-back range.

Figure 12 (below). Load current changes, obtained by averaging load current from Figures 10 and 11 over one half-cycle

Figure 13 (right). Theoretical wave shapes for ampere turns for positive feedback

Because the characteristics in Figures 6, 7, 8, and 9 were derived directly from the master graph (Figure 5), it is obvious that Figures 6, 7, 8, and 9 also embody feedback. The positive feed-back multiplier m_1 is larger than unity and the negative feed-back multiplier m_2 is smaller than unity. In the characteristics shown in Figures 6, 7, 8, and 9, selection between m_1 and m_2 has to be made depending on whether the feedback is positive or negative, and the notation $m_{1,2}$ means either multiplier.

The effect of feedback is demonstrated in Figure 14 for the case of $N_F=400$, $N_L=592$, otherwise having the same parameters as the case I_L versus I_C. By comparison with Figure 6 (no feedback), the slope of the proportional region OB for positive feedback is $m_1 \cdot 0.676$ (in Figure 14) and the slope of the proportional region OA' for negative feedback is $m_2 \cdot 0.676$.

While the characteristics without feedback (Figure 6) are symmetrical with respect to the ordinate axis, the characteristics with feedback become unsymmetrical. For large values of m_1, the measured characteristic OB is shifted somewhat to the left of the theoretical position due to the finite magnitude of the magnetizing ampere turns (see Figure 5, vicinity of O) which are now amplified by the positive feed-back circuit, and also due to the width of the hysteresis loop.

If the reverse current in the feed-back rectifier is not zero, the current flowing through the feed-back winding is smaller than the load current. As a result the effective value of m_1 appears somewhat smaller than calculated from equation 40. For large values of m_1 the control ampere turns are small and become comparable to the magnetomotive force necessary to produce a given flux in the core. In this case, our assumption of infinite slope of the magnetization curve up to saturation flux density is no longer a valid assumption. The numerical accuracy of the various expressions will be lessened, but the general trend is still correctly reflected by equation 40: as the number of feed-back turns N_F is increased the gain of the saturable reactor is increased and may reach infinity. If the number of feed-back turns is increased beyond this point, snap action sets in and the saturable reactor behaves somewhat similar to a latch type relay.

Response with Feedback

The application of feedback also has a significant effect upon the response of the saturable reactor. The total flux swing $\Phi_{\Delta,m}$ (equation 17) now becomes

$$\Phi_{\Delta,m}=\frac{10^8}{4fN_L}(E-m_{1,2}I_C R_L N_C/N_L) \qquad (46)$$

and the apparent inductance L_C

$$L_C=m_{1,2}\frac{\Delta(\phi_A+\phi_B)}{\Delta I_C}N_C 10^{-8}=m_{1,2}\frac{R_L}{4f}\frac{N_C^2}{N_L} \qquad (47)$$

With the reservations set forth in the following paragraph the time constant in cycles becomes proportional to the multiplier $m_{1,2}$ and therefore it can be expressed by the following equation

$$T=m_{1,2}\frac{1}{4}\frac{R_L}{R_C''} \qquad (48)$$

In the preceding, where only two coupled circuits on each reactor were involved, the time constant for rise and fall is the same (Figure 12). With the application of feedback, a third winding is introduced and, in combination with the feed-back rectifier, transient currents can flow which have not been accounted for in the previous considerations.

Suppose positive feedback is applied and the control voltage is suddenly raised. By this action a voltage is induced in the feed-back windings which is positive at terminals Z_1. This voltage attempts to drive a current through the following path (Figure 2): *15-10-9-8-7-6*, but the circuit cannot be closed from *6* to *15* because of the blocking action of the rectifier. Thus, a transient current in the feed-back circuit cannot flow for a rise of control voltage, and therefore the expression of equation 48 for the time constant is applicable.

Now, let the control voltage E_C suddenly drop. This induces voltages in the feed-back windings which are positive at terminals Z_2. These voltages are now driving a transient current through the path: *15-6-7-8-9-10-15*, passing the feed-back rectifier in the forward direction. We conclude that the decaying flux is now interlinked with two windings in parallel, namely the control winding and the feed-back winding. As seen from the core, the resistance of the control winding has been reduced by paralleling it with the resistance of the feed-back winding, referred to the control winding. The effect of this apparent reduction of R_C' is an increase of the time constant (equation 48) for the fall direction. One concludes that in the presence of feedback two different time constants exist for rise and fall. For positive feedback and rise, $R_C''=R_C'$ (equation 32); for fall, R_C'' is equal to R_C' and R_F' in parallel, where

$$R_F'=R_F\frac{N_L^2}{N_F^2} \qquad (49)$$

A portion of the rectifier forward resistance should be included in R_F.

For negative feedback (region OA', Figure 14) a rise in negative control voltage will cause a transient current through the feed-back circuit and therefore R_C'' equals the parallel connection of R_C' and R_F'. For a drop of negative control voltage, the double interlinkage is prevented by rectifier blocking and therefore $R_C''=R_C'$.

As in the case without feedback, equation 48 does not hold for very small per unit load current. In this region the response is delayed to a far greater measure than expressed by equation 48.

When operated in the overexcited region (DD' in Figures 5, 6, and 14), no change in net flux occurs, and therefore the response is practically instantaneous.

Figure 14. Load current I_L as function of control current I_C with feedback

Solid lines are calculated, dots are measured points

Rectifier Rating

The current rating of the feed-back rectifier is determined by the magnitude of the load current I_L. The voltage rating is determined by the peak-inverse voltage. Suppose the load current is flowing at this moment from *2* (Figure 2) to *6*, through the instrument, *7-8*, feed-back windings, and *15* to *3*. The current flowing from *6* to *3* causes voltage drops in the resistance of the various components just listed and also in the leakage reactance of the feed-back windings. These voltage drops appear as peak inverse voltage on the rectifier cell between *6* and *3*, and an equal amount between *15* and *2*. It will be observed that these voltage drops are small in comparison with the line voltage. In order to make the a-c component of i_C, see Figure 13, flow through the control circuit with its resistance R_C, an alternating voltage must be induced in the control windings. The feed-back windings are linked in the same way as the control windings, and therefore the alternating voltages are also induced in the feed-back winding. The net peak inverse voltage across the rectifier is obtained by the joint action of the voltage drops and induced voltages. Practically, this net peak-inverse voltage is usually very small by comparison with the line peak voltage and therefore a single selenium rectifier cell in each branch of the bridge rectifier is often sufficient where the line voltage is 115 volts rms. One recognizes that the rating, size, and cost of the feed-back rectifier will be only a fraction of the power rating of the magnetic amplifier.

Current Gain

It is defined by

$$K_i = \frac{I_L}{I_C} = m_{1,2}\frac{N_C}{N_L} \tag{50}$$

as can be verified from equations 38 and 44. Because of the instantaneous relation of ampere turns (equation 9), no time delay is involved for $m_{1,2}=1$. For $m_{1,2}\neq 1$ transients may occur in the feed-back windings, with similar directional effects as discussed for the time constant.

Voltage Gain

The voltage gain K_e is expressed by the ratio $I_L R_L/E_C$. Using operational notation,[8] the transfer function[9] of the voltage gain can now be written in the form

$$K_e G(p) = \left(m_{1,2}\frac{R_L}{R_C}\frac{N_C}{N_L}\right)/(1+pm_{1,2}T) \tag{51}$$

It should be pointed out that the multiplier $m_{1,2}$ affects gain and effective time constant in the same manner.

Power Gain

This gain is defined as the ratio of output power over control power

$$K_p = \frac{I_L^2 R_L k_f^2}{E_C I_C} = \frac{I_L}{I_C}\frac{I_L R_L}{E_c}k_f^2 = K_i K_e k_f^2 \tag{52}$$

Substituting from equations 51, 52, and 32

$$K_p = m_{1,2}^2 k_f^2 R_L/R_C' \tag{53}$$

The application of positive feedback increases the steady-state power gain to m_1^2 times. The effective time constant is increased to m_1 times; it should be remembered that the time constants T are different for rise and fall, and therefore two different values for the time constant T exist. The following remarks are directed to the rise of positive control voltage.

A speed-up of response can be obtained by placing an external resistance in series with the control winding, thus effectively increasing R_C. The result is a reduction of time constant and a proportional reduction of power gain.

If a saturable reactor is supplied with positive feedback m_1, and at the same time an external resistor is placed in series with the control winding such that the total control-circuit resistance becomes $m_1 \cdot R_C$, the time constant of the saturable reactor remains the same

$$m_1 \frac{R_L}{m_1 R_C'}\frac{1}{4f} = T \tag{54}$$

Under these circumstances the power gain K_p of the saturable reactor is

$$K_p = m_1^2 k_f^2 R_L/R_C' m_1 = m_1 k_f^2 R_L/R_C' \tag{55}$$

Comparing the saturable reactor without feedback to the one with feedback, we see that for equal time constants, the positive feedback results in a power gain of m_1 times over the case without feedback. It is obvious from the preceding that the application of positive feedback greatly improves the performance of magnetic amplifiers.

Appendix. List of Symbols

B = flux density, gauss
B_s = saturation flux density, gauss
e = line voltage, instantaneous value, volts
E = line voltage, rectified average, volts
E_m = line voltage, crest value, volts
$E_{s,0}$ = no-load saturation voltage, rectified average, volts
E_C = control voltage, average, volts
E_C' = control voltage referred to load winding, average, volts
$e_{L,A}, e_{L,B}$ = voltage across load winding A or B respectively, instantaneous value, volts
f = line frequency, cycles per second
F_A, F_B = magnetomotive force in core A or B respectively, gilberts
$G(p)$ = a function of p
H = magnetic intensity, oersted
H_s = magnetic intensity at which saturation flux density occurs, oersted
i_L = load current, instantaneous value, amperes
I_L = load current, rectified average, amperes
$I_{L,m}$ = maximum load current, rectified average, amperes
$I_{L,min}$ = smallest possible load current, average, amperes
$I_{L,eff}$ = load current, rms, amperes
$i_{L,A}, i_{L,B}$ = current in load winding A or B respectively, instantaneous value, amperes
i_C = control current, instantaneous value, amperes
I_C = control current, average, amperes
i_F = current in the feed-back winding, instantaneous value, amperes
I_F = current in the feed-back winding, average, amperes
K_e = voltage gain, unity
K_i = current gain, unity
K_p = power gain, unity
k_f = form factor, unity
L = inductance, henrys
L_C = apparent inductance of complete control circuit, henrys
m_1 = feed-back multiplier for positive feed-back, unity
m_2 = feed-back multiplier for negative feed-back, unity
$m_{1,2}$ = either feed-back multiplier, unity
N_C, N_L, N_F = number of turns of one control winding, one load winding, and one feed-back winding, respectively
p = operator d/dt
R_L = load-circuit resistance, ohms
R_C = control-circuit resistance, ohms
R_C' = R_C referred to load winding, ohms
R_F = resistance of feed-back circuit, ohms
R_F' = R_F referred to loading winding, ohms
R_C'' = effective resistance of control windings and feed-back windings during transient operation, as seen from load winding, ohms
t = time, seconds or cycles
T = time constant, seconds or cycles
α = angle of retard, degrees or radians
θ = electrical angle, degrees or radians
ξ = per unit excitation, unity
π = 3.14159
ϕ_A, ϕ_B = core flux in core A or B respectively, instantaneous value, maxwells
$\phi_{\Delta,A}$, $\phi_{\Delta,B}$ = flux change in core A or B respectively, instantaneous value, maxwells
$\Phi_{\Delta,m}$ = maximum flux change, maxwells
Φ_s = saturation flux, maxwell
Φ_1 = core flux in core A at $\theta=0$, maxwells
ω = angular velocity of θ, radians per second

Effects of Supply Line Unbalance on the Filtered Output Ripple of Polyphase Rectifiers

C. K. HOOPER
ASSOCIATE AIEE

C. H. McADIE
ASSOCIATE AIEE

RECTIFIERS are often used when direct currents are obtained from a-c sources. Some of these d-c loads require a minimum of ripple in the applied voltage. This is particularly true in the case of electronic communication equipment, for example broadcast transmitters. Output filters in the direct current are practically always used in these cases, as the inherent ripple normally present in the output of rectifiers is too great to be tolerated.

For the larger loads, polyphase rectifiers are preferred to single-phase rectifiers. One of the reasons for this is that the d-c voltage at the output of a polyphase rectifier has a lower value of a-c component than in the d-c output of a corresponding single-phase rectifier. Another advantage of the polyphase rectifier is that the lowest frequency of a-c component in the direct current is normally higher than for a single-phase rectifier.

The inherent condition of low-ripple voltage and high-ripple frequency simplifies the filtering problem. The results of this can readily be observed by comparing the filter components of a polyphase rectifier with those of a single-phase rectifier of the same rating and output ripple. The filter components used with the polyphase rectifier are much smaller. But, in the case of a polyphase rectifier, if the a-c supply line voltages are not exactly balanced, then additional components of ripple voltage will be present in the d-c output and these added components will have a frequency lower than that normally present when the a-c supply voltages are balanced.

In most power distribution systems in use today, the polyphase voltages are quite well balanced. Any slight unbalance which may exist is therefore frequently ignored in the design and application of polyphase rectifiers. However, particularly in the case of rectifiers having filtered output, the effects of line unbalance, even of the small amounts commonly encountered, are such as to often result in unsatisfactory rectifier performance. In particular, the magnitude of the ripple voltage in the d-c output may be much higher than expected.

As an example standard *TR-101-A* published by the Radio Manufacturers Association (RMA)[1] states in paragraph 16b(2) that . . . "for 3-phase power supplies the full load voltage from phase-to-phase shall be within 2 per cent of the average of the three phases. . ." The radio transmitter performance is expected to comply with all operating standards under these conditions of supply line unbalance. This same requirement also appears in RMA standard *TR-104* for Electrical Performance of Television Broadcast Transmitters.[2]

Polyphase rectifiers using filters of the types commonly required in broadcast service will show a marked increase in output ripple voltage as the line unbalance changes from 0 to the 2 per cent limit permitted by the RMA standards. Actually the amplitude of the ripple voltage may increase over 400 per cent as the line unbalance increases from 0 to 2 per cent. It therefore can be seen that the effects of line unbalance of even small amplitude should not be neglected in polyphase rectifier filter designs.

The following discussion applies specifically to 3-phase double-way rectifiers. However, the same equations and curves also apply to 6-phase single-way rectifiers. Most applications requiring polyphase filtered power supplies use either of these two types of rectifier circuits. Methods of determining the effect of line unbalance on the output ripple of a filter rectifier are given. The required filter modifications also can be determined should it be desired to overcome the effects of line unbalance. The relative amplitude of the original ripple component and that of the lower frequency component resulting from line unbalance also can be determined readily for various values of line unbalance.

A conventional circuit of a 3-phase double-way rectifier having a single section choke input filter is shown in Figure 1. The direct voltage appearing in the output of a 3-phase double-way rectifier without being filtered is shown in Figure 2. The solid line shows the envelope of the direct voltage. This envelope is not a straight line but is seen to consist of periodic pulsations each of equal amplitude and similar shape. The lowest frequency component of these pulsations is six times the supply line frequency and the rms amplitude of this lowest frequency component is 4.04 per cent of the average direct current. This relationship is well known and is derived in standard texts on this subject.[3] Figure 3 is an oscillogram of the unfiltered rectified output obtained with a balanced supply. Figure 4 is similar to Figure 2 except that the a-c supply voltage is shown as unbalanced. In this case it can be seen that while the d-c envelope contains pulsations as before, the successive pulsations are no longer identical. As an approximation, the variations in successive pulsations can be represented as

Paper 50-125, recommended by the AIEE Electronic Power Converters Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Great Lakes District Meeting, Jackson, Mich., May 11-12, 1950. Manuscript submitted February 9, 1950; made available for printing March 24, 1950.

Figure 1 (left). Diagram of a 3-phase double-way rectifier with a single section low pass filter

Figure 2 (right). Envelope of 3-phase double-way rectifier output voltage with balanced supply line

the equivalent of uniform pulsations plus a superimposed pulsation of lower frequency as shown by the dotted line. This lower frequency pulsation is seen to have a frequency of two times the supply line frequency. Also the amplitude of this lower frequency component can be seen to vary with the amount of line unbalance being zero for a balanced line. Figure 5 is an oscillogram of the unfiltered rectified output obtained with an unbalanced supply.

The relationship between the amplitude of this double frequency component and amount of unbalance is given in equation 4 of the Appendix. (The development of this equation and those which follow are given in the Appendix. The numbers of equations in this section refer to similar equations appearing in the Appendix.)

$$E_{2p} = K \tag{4}$$

where E_{2p} is the rms amplitude of the $2fo$ component in per cent of direct voltage, K is the amount of line unbalance expressed in per cent, and fo is the frequency of the supply line.

The curves on Figure 6 show the $2fo$ and $6fo$ components of ripple in the output of a 3-phase double-way rectifier as a function of line unbalance. The combined value of the $2fo$ and $6fo$ component also is shown as this same figure.

If the supply line is balanced, the relationship between the filter constants and the desired output ripple amplitude can be expressed by

$$E_{4a} = \frac{4.04}{(6\times 2\pi fo)^2 LC - 1} = \text{output ripple voltage (rms, in per cent of the average direct voltage)} \tag{7}$$

where

fo = supply line frequency
L = inductance in henrys
C = capacity in farads

Higher frequency components are appreciably smaller and can be neglected in this over-all rms relationship: Now if the a-c supply line voltage is unbalanced there will then be present in the d-c output a ripple component E_{2a} of frequency $2fo$ and this will be in addition to the output ripple E_{4a} of frequency $6fo$.

E_{2a} is determined as follows

$$E_{2a} = \frac{K}{(2\times 2\pi fo)^2 LC - 1} = 2fo \text{ component of output rms voltage resulting from line unbalance. (Expressed as a per cent of the average direct voltage)} \tag{8}$$

The basis $6fo$ component is unaffected by the amount of line unbalance and the resulting rms output ripple is the combined total of E_{4a} and E_{2a}.

Let the ratio

$$N = \frac{E_{1a}}{E_{4a}}$$

where E_{1a} is ratio of total output ripple voltage under conditions of line unbalance to the output ripple under conditions of balanced line. Approximately, for conditions applying when the output is well filtered this ratio N can be expressed by

$$N = \sqrt{5(K)^2 + 1} \tag{12}$$

It is thus seen that the increase in output ripple in terms of the ripple existing under balanced conditions is dependent only on the degree of unbalance. The supply line frequency and the filter constants have no effect on this relationship. Figure 10 shows this relationship in curve form. For example, it can be seen that for a 2 per cent unbalance, the resulting output ripple is 4.5 times the value which would be obtained with a balanced supply.

Figures 7, 8, 9 are oscillograms showing the filtered output for various amounts of unbalance. Since all oscillograms were taken to the same scale it will be seen that a large increase in ripple results from a comparatively small increase in unbalance.

The curve shown on Figure 10 also can be used to determine how much additional filtering is required to overcome the effect of a given amount of supply unbalance. For example, assume that an output ripple of 0.05 per cent maximum is required for all values of line unbalance up to 3 per cent. From Figure 10 it is seen that at 3 per cent line unbalance the ripple amplitude is 6.7 times as great as for zero unbalance. Thus a filter must be designed which will limit the ripple to 0.05/6.7 or 0.0075 per cent at zero unbalance. From fundamental relationships or from filter calculation charts[4,5] it can be determined that the inductance-capacitance product to give 0.0075 per cent ripple is 100 for a 60-cycle supply. That is the product of the inductance in henrys, times the capacity in microfarads, must equal at least 100. For balanced line conditions, however, the inductance-capacitance product corresponding to 0.05 per cent ripple is only 16. Thus, since the size and cost of a filter is roughly proportioned to its inductance-capacitance product, then a 3 per cent line unbalance is seen to require about 100/16 or 6.3 times as much filter.

As the line unbalance increases, the percentage of $2fo$ component in the filtered output increases rapidly in comparison with the basic $6fo$ component. For example, an unbalance of 1 per cent will result in the $2fo$ component being about 90 per cent, and the $6fo$ component being about 40 per cent of the total output ripple. Figure 11 shows in curve form the distribution of the $2fo$ and $6fo$ components for various values of line unbalance. The relationship expressed in equation 12 and Figure 10 is approximate only. It is, however, reasonably accurate whenever filters having comparatively large attenuations are used. When filters of moderate or small attenuations are used the curve becomes less accurate. For example: if a filter having an inductance-capacitance product

Figure 3. Oscillogram of unfiltered 3-phase double-way rectifier output voltage with balanced supply line

Figure 4 (left). Envelope of unfiltered 3-phase double-way rectifier output voltage with unbalanced supply line

Figure 6 (right). Output ripple voltage from a 3-phase double-way rectifier as a function of line unbalance

of 15 is used with a 60-cycle supply, then the approximate methods give an output ripple of 0.0525 per cent for a balanced line and 0.24 per cent for a 2 per cent line unbalance. If a more accurate analysis is made the output ripple under balanced conditions is 0.053 per cent and 0.27 per cent for 2 per cent unbalance. The error resulting from the use of approximate methods is seen to be small in this case and can usually be neglected.

Consider, however, a filter having an inductance-capacitance product of three with a 60-cycle supply. In this case the approximate methods give an output ripple under balanced line conditions of 0.26 per cent and for a 2 per cent line unbalance, 1.20 per cent. However, if a more accurate calculation is made, the corresponding ripple amplitudes are 0.28 per cent for balanced conditions and 2.85 per cent for a 2 per cent unbalance. For the filter combinations assumed in the later case, the discrepancy between the values obtained by approximate methods and those obtained by more accurate methods are probably too great for practical use. This is particularly true when line unbalance conditions exist.

As a practical consideration, however, in most cases where filtered direct current is required, the effectiveness of the filter is usually large enough so that the Figure 10 can be used with reasonable accuracy.

Figure 12 shows the value of output ripple as affected by the size of the filter components and for several values of supply line unbalance. This curve is more limited in scope and is less convenient to use than the curve shown in Figure 10. However, if because of small filter requirements the assumptions upon which Figure 10 is based are not valid, then a more correct result can be obtained from Figure 12.

Figure 5. Oscillogram of unfiltered 3-phase double-way rectifier output voltage with 2.7 per cent line unbalance

Appendix

Ripple measurements made on a 3-phase double-way test rectifier with a harmonic analyzer indicate that the amount of $2fo$ components varies linearly with line unbalance. It can be represented by

$$E_2 = 1.35 \times \frac{K}{100} \times E_{avg} \qquad (1)$$

where

E_{avg} = rms line-to-line voltage (average of the three line-to-line values)
K = per cent maximum deviation from E_{avg}
E_2 = $2fo$ ripple rms volts
fo = supply line frequency

In order to put this in terms of the no load direct voltage, the following standard relations between the input alternating voltage and output direct voltage of a 3-phase double-way rectifier are used

$$E_{dc} = 1.35 E_{avg} \qquad (2)$$

$$\therefore E_2 = \frac{K}{100} E_{dc} \qquad (3)$$

or dividing by E_{dc} and multiplying by 100 to get E_2 as a percentage of the no-load d-c voltage.

$$E_{2p} = K \qquad (4)$$

where E_{2p} is the rms amplitude of the $2fo$ component in per cent of the direct current.

The amplitude of the $6fo$ component was found by the harmonic analyzer to remain essentially constant for varying amounts of line unbalance, therefore is the same as the theoretical amount at zero line unbalance.

$$E_{6p} = 4.04 \text{ per cent} \qquad (5)$$

where E_{6p} is the rms amplitude of the $6fo$ component in per cent of the no load direct current.

The total rms ripple is made up of a combination of the $2fo$ and $6fo$ components which since they are of different frequencies combine to give

$$E_t = \sqrt{E_{2p}^2 + E_{6p}^2} = \sqrt{16.4 + K^2} \qquad (6)$$

E_t = total rms ripple amplitude as a per cent of the d-c voltage.

Effects of Filtering

If a filter is used of a type shown in Figure 1, the amplitude of the output ripple with a

Figure 7. Oscillogram of the filtered output of a 3-phase double-way rectifier with balanced supply line

Figure 8. Oscillogram of the filtered output of a 3-phase double-way rectifier with 0.7 per cent line unbalance

Figure 9. Oscillogram of the filtered output of a 3-phase double-way rectifier with 14.0 per cent line unbalance

Figure 10 (left). Ratio of ripple voltage increase in the filtered output of a 3-phase double-way rectifier as a function of line unbalance

Figure 12 (right). Output ripple from a single stage low pass choke input filter used with a 3-phase double-way rectifier as a function of filter constants

balanced supply line is attenuated and is given[2] by

$$E_{4a} = \frac{4.04}{(6\times 2\pi fo)^2 LC - 1} \tag{7}$$

where

E_a = the rms amplitude of the $6fo$ component as a per cent of d-c voltage
L = the inductance in henrys
C = the capacity in farads
$R > 1/(2\times 2\pi foC)$

If the supply line is unbalanced then an additional component of ripple appears in the output of the filter and its amplitude is given by

$$E_{2a} = \frac{K}{(2\times 2\pi fo)^2 LC - 1} \tag{8}$$

where E_{2a} = the rms amplitude of the $2fo$ component in terms of d-c voltage.

As a simplifying approximation, if $(2\times 2fo)^2 LC$ is large compared with one, then E_{4a} and E_{2a} can be combined in a manner similar to equation 6 to give

$$E_{1a} = \frac{1}{(2\times 2\pi fo)^2 LC} \times \sqrt{K^2 + \left(\frac{4.04}{9}\right)^2} \tag{9}$$

where E_{1a} is the rms amplitude of the total output ripple as a per cent of the direct voltage.

If the filter under balanced conditions is effective in reducing the ripple to 0.05 per cent or less (a value commonly used in electronic applications) then the values obtained from equation 9 are accurate to within about 10 per cent.

Equation 9 simplifies to the following for 60-cycle and 50-cycle cases.

$$E_{1a(60\ cy)} = \frac{1.79}{LC'} \sqrt{K^2 + 0.2} \tag{10}$$

L = inductance of filter choke in henrys
C' = capacitance of filter capacitor in microfarads

$$E_{1a(50\ cy)} = \frac{2.54}{LC'} \sqrt{K^2 + 0.2} \tag{11}$$

By dividing equation 9 by itself with K, set equal to zero we obtain the ratio of increase in filter output ripple with increases in line unbalance.

$$N = \frac{E_{1a}}{E_{4a}} = \sqrt{\frac{K^2 + 0.2}{0.2}} = \sqrt{5(K)^2 + 1} \tag{12}$$

This equation is plotted as Figure 10.

It should be noted that the actual filter values and line frequency disappear from this relation, thus giving the ratio of increase in filter output ripple as a function of line unbalance only.

A simple relation between $2fo$ and $6fo$ components is obtained by dividing equation 7 by equation 8

$$\frac{E_{2a}}{E_{4a}} = \frac{9}{4.04} K = 2.23K$$

Figure 11. Relative amplitude of ripple components in the filtered output of a 3-phase double-way rectifier as a function of line unbalance

which shows that the ratio of $2fo$ and $6fo$ component is 2.23 times the line unbalance.

The percentage that each of the ripple components represent of the total is found by dividing equations 7 and 8 by equation 9. The percentage of $2fo$ in the total ripple, dividing equation 8 by equation 9 is

$$P_2 = \frac{\dfrac{K}{(2\times 2\pi fo)^2 LC} \times 100}{\dfrac{1}{(2\times 2\pi fo)^2 LC}\sqrt{K^2 + 0.2}} = \frac{K \times 100}{\sqrt{K^2 + 0.2}} \tag{13}$$

and the percentage of $6fo$ in the total ripple dividing equation 7 by equation 9 is

$$P_6 = \frac{\dfrac{4.04}{(6\times 2\pi fo)^2 LC} \times 100}{\dfrac{1}{(2\times 2\pi fo)^2 LC}\sqrt{K^2 + 0.2}} = \frac{45}{\sqrt{K^2 + 0.2}} \tag{14}$$

In each of these cases the final minus one in the denominator of equation 7 and 8 has been dropped.

Where less effective filters are used, resulting in output ripple amplitude larger than 0.05 per cent the approximations previously made are no longer sufficiently accurate. In these cases the amplitudes of the $2fo$ and $6fo$ ripple components must be individually calculated from equations 7 and 8, and then the total ripple will be obtained by taking the square root of the sum of the components.

Values calculated in this manner for 50- and 60-cycle supply line frequencies and for 0, 2 per cent, and 5 per cent line unbalance are shown on Figure 12. Where the values of capacitance and inductance of the filter are less than those set by the limits indicated on

Figure 12, the ripple will be less than indicated by the curves. In the case of inductance lower than the limit, increased regulation, usually undesirable, decreases the ripple amplitude.

In case the capacity values are lower than the limit, a condition normally not encountered, the effect of the load resistance in reducing the a-c shunt impedance results in further reducing ripple amplitude.

No Discussion

A New High Interrupting Capacity Low-Voltage Power Fuse

C. L. SCHUCK
ASSOCIATE AIEE

A NEED exists for low-voltage fuses having much higher short-circuit interrupting capacity than cartridge fuses commonly used.

Cartridge fuses for circuits 600 volts and less have been used in the United States for many years, principally in low burden branch circuits where available fault currents were relatively low. They are produced by numerous manufacturers, and practically all makes satisfy the National Electric Code through compliance with the Standard for Fuses[1] of Underwriters' Laboratories, Inc.

In the matter of short-circuit interrupting ability, the Standard for Fuses includes a d-c test with 10,000 amperes available, the rate of rise of the Underwriters' Laboratories New York City testing circuit being approximately 2,000,000 amperes per second. While most applications of cartridge fuses are on a-c circuits, this d-c short-circuit test is, even today, the only criterion in use for determining the acceptability of fuses for application on either a-c or d-c circuits.

However, no direct inference is valid concerning the a-c short-circuit interrupting ability of a fuse which has passed this particular test. Table I shows limiting values of 60-cycle symmetrical available short-circuit current safely interrupted by members of a typical line of cartridge fuses, all of which passed the Underwriters' d-c 10,000 ampere short-circuit acceptance test.[2] These were nonrenewable, nonindicating fuses.

Conversely, the a-c short circuit interrupting ability demonstrated for a fuse is not a reliable indication of its ability to interrupt a d-c short circuit. Although some efforts have been made to establish a theoretical relation between a-c and d-c interrupting ability,[3] interruption tests on a circuit of the same type as that on which applications are intended are the only reliable basis for assigning interrupting ratings.

National Electric Code Cartridge Fuses

Cartridge fuses as manufactured in the United States, through standardization of dimensions and melting time-current and temperature rise specifications of the Standard for Fuses have become extremely low cost devices. Practically all makes employ a link of zinc wire or strip surrounded by a granular or powder filler (or merely air) and are enclosed in a rolled paper or fiber tube with brass or copper ferrules. Some makes incorporate special features such as time-lag in the melting characteristic, field renewability, and so forth, but with one recent exception,[4] none of the numerous manufacturers, to the writer's knowledge have published a-c or d-c interrupting ratings or d-c ratings other than those implied by Underwriters' Laboratories, Inc., approval based upon the 10,000-ampere test value. In recent years, however, the progressive increase in the short-circuit currents possible on many networks, industrial circuits, station auxiliary, and shipboard circuits, has led to the demand for fuses actually having interrupting ability to cover these present day requirements, which are in many cases greatly in excess of 10,000 amperes rms.

European Developments

In Europe, and principally in Great Britain and Germany, cartridge fuses of proved high-interrupting capacity have been in use for some years. Their development evidently was spurred by efforts to conserve strategic materials, leading to their application in many cases where it is the American practice to use circuit breakers. Also, there do not appear to have been available in Europe any counterparts of the mass-produced low-cost National Electric Code fuses. Fuse development in England was accompanied by considerable research on the fuse design factors and circuit parameters to determine their effect on interrupting ability, with the result that the high-capacity fuse designed according to these findings could justly be described by Gibson[5] as "in its more advanced forms a reliable piece of apparatus with a precision performance."

The European high-capacity fuse for low-voltage service was of the same basic construction as the current limiting fuses already well established for high-voltage applications,[7] having metallic links embedded in a granular inert filler. The current limiting manner of interruption resulting from this construction when properly designed, minimized the energy dissipated in the fuse cartridge to the ex-

Paper 50-127, recommended by the AIEE Switchgear Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Great Lakes District Meeting, Jackson, Mich., May 11–12, 1950. Manuscript submitted February 14, 1950; made available for printing March 24, 1950.

C. L. Schuck is with the General Electric Company, Philadelphia, Pa.

A—British high rupturing capacity fuse
B—German 350-volt 200-ampere fuse for shipboard

tent that external disturbance was eliminated and interrupting ratings could be assigned of 44,000 symmetrical rms amperes for 660-volt circuits.

Although no standardization of dimensions had been found practical in Great Britain, "high-rupturing-capacity" fuses were developed to occupy minimum space, and for given ampere ratings have diameters of the same order as American National Electric Code fuses, but shorter cartridge lengths. The cartridges usually are made of heavy-walled ceramic material, having separate holes isolating the parallel element components and the resulting arcs formed during interruption. The holes are filled around the elements with granular quartz similar to that used in high-voltage current limiting fuses, Figure 1(A). The transient pressure must still have constituted a considerable problem in view of the thickness of ceramic used. In German fuses for submarines, a substantial portion of the cartridge length was reinforced with a steel jacket, Figure 1(B).

Interrupting Rating

In commencing the development of a line of high-interrupting capacity cartridge fuses suitable for manufacture here, it was realized that interrupting ability beyond the 44,000-rms ampere rating of the British designs would be necessary to satisfy the requirements of many American industrial and shipboard circuits. A rating of 100,000 total rms amperes, (including d-c component) appeared to be the most satisfactory objective, so as to permit application on systems where circuit breakers of this rating are required in some circuits. The 100,000-rms ampere rating in the case of a 3-pole circuit breaker implies an available symmetrical short circuit current of 80,000-rms amperes, the factor accounting for the d-c component and average current among the phases being 1.25, as explained in a recent AIEE paper, Guide for Applying Low-Voltage Air Circuit Breakers.[8] (See Appendix I).

Tube Material

Efforts toward obtaining the desired interrupting capacity were aided considerably by the availability from several American manufacturers of glass-cloth-base, heat-resistant resin-impregnated insulation in tube form. The strength and resilience of such tubes was found more than adequate to withstand the transient pressures occurring during interruption with even more than the maximum element section usable, as determined from time-current melting, and maximum temperature limits. Thus the problems associated with thick-walled ceramic tubes, reinforcement, and so forth were avoided.

Filler

Another asset available here for the development of fuses with higher interrupting capacity was a specially graded granular quartz filler developed for high-voltage current-limiting power fuses,[9] where grain sizes are restricted to the range which provides maximum grain surface for withdrawing heat from the arcs, and at the same time provides the intergranular air spaces required for the dispersal of the element metal.

Element Design

In addition to advantages gained by the use of the woven glass base tube material and the improved filler, it was considered desirable to make use of any further advances that might result from improvements in the element proportions. As a general conclusion based on interrupting test results, it was found that substantial length was not required in the arc paths for the low-circuit voltages involved. This differs from findings in high-voltage fuse developments.[9] As circuit voltage was causing no particular hardship, the minimization through the use of short active element sections of the amount of metal which became involved in the arcs could be credited with much of

Figure 2 (left). X-ray photograph of unopened developmental fuse samples after short-circuit tests

Figure 3 (right). Same fuse samples as in Figure 2 cutaway showing the "fulgurites" formed by the arc current

the improvement obtained in interrupting ability.

The division of the element section required for a given ampere rating into a number of spaced parallel paths was found to aid in the prompt development of arc voltage, in limiting transient pressure in the cartridge, and thereby in further increasing the interrupting ability.

The degree of division of element section when carried sufficiently far was found to provide interrupting ability well above the 100,000-rms ampere objective. Carried too far, extreme subdivision with the required spacing between elements calls for more fuse tube cross-section than would be practical or economical. For adequate interrupting ability, with an acceptable pattern of element spacing, the number of parallel arc paths was found to be significant.

It was found that the number of rated amperes per single element necessary for the safe interruption of 100,000-rms amperes should be substantially less than the amperes per element of European designs. This further reduction in the amount of element metal which becomes involved in any one arc path is the factor believed chiefly responsible for the greater interrupting ability found possible.

These factors, together with the spacing between arcs, and from any arc to the inner surface of the fuse tube, were investigated in a series of d-c short-circuit tests, using samples in which the element designs differed from one sample to the next by definite increments. As criteria of the difficulty with which the fuse sample opened the circuit, use was made of the temperature rise of the cartridge following the test, oscillograms, X-ray photographs, and ordinary photographs and examination of the fuse samples cut-away to show the elements. Figure 2 shows an X-ray photograph of typical unopened test samples following d-c short-circuit interruption tests. They show the degree of dispersion of element metal caused by the arcing. Figure 3 shows

Total time, seconds	0.0029	0.0089

the same samples cut-away with excess quartz removed to expose the remains of the elements. By study of the size of "fulgurite" or slag formation where the arcs had fused the granular quartz filler, and the other means mentioned previously the influence of each of the several factors was assessed, and conclusions were reached concerning:

1. Number of elements (arcs in parallel).
2. Number of reduced sections (arcs in series).
3. Spacing between parallel arcs.
4. Spacing between arcs in series.
5. Spacing of any arc to inner wall of fuse tube.
6. Mass of terminals—path to ferrules.
7. Type of filler.

From these observations followed the optimum dimensions and other data around which a line of high-capacity fuse elements could be designed.

A d-c circuit was employed for these tests in view of results of numerous earlier short-circuit tests in which a given fuse design performed well in interrupting an a-c circuit, but not as well in a d-c circuit. The salient factor making for greater severity in the d-c tests was evidently the sustained voltage, which caused arc current to persist, while in the a-c tests the falling voltage enabled the fuse to force current to zero at or before the first voltage zero following melting, sufficient deionization of the arc paths then taking place to prevent re-establishment of the arcs during the subsequent half cycle or thereafter. Figure 4 shows oscillograms of an a-c and d-c short-circuit test on developmental fuse samples of the same design, the arc current falling rapidly with decreasing voltage and ceasing before voltage zero in the 60-cycle a-c test, arcing time being 0.0026 second, but persisting for 0.0083 second (equivalent to a full half cycle) in the d-c test. Once this was noted, efforts were directed toward so designing the elements as to combat the development of the trailing arc current on d-c tests, and its duration was employed as one of the criteria of good element design.

Dimensions and Melting Requirements

Based on the data accumulated, it appeared that it would be perfectly possible to make the line of high-interrupting capacity cartridge fuses in the same cartridge sizes as conventional National Electrical Code fuses, even in the case of the 250-volt 30-ampere rating which appeared to be the "tightest" on the basis of the values in Table II.

In order fully to meet the requirements of the Standard for Fuses,[1] elements had to be so designed as to melt within specified times at given percentages of overload current, and on normal current to generate heat at a rate sufficiently low so as not to overheat the fuses themselves nor connected devices such as knife switches, contactors, and so forth. The requirements are summarized in Table III.

"M" Effect

With respect to active element section required, the above specifications are contradictory, requiring a large cross section for the 110 per cent cool-running requirement, and a small cross section for the overload prompt-melting requirement. This problem was solved by use of the so-called "M" effect,[16] obtained by the addition of small globules of a tin-rich alloy to the active sections of the elements. On overload, the elevated temperature causes local alloying and diffusion of the silver element metal into the tin, the resulting alloy having both a

Table III. Temperature Rise and Overload Melting Requirements of the Underwriters' Laboratories Inc., Standard for Fuses

* Fuse must operate within times listed.

Figure 5. Melting time-current curves. Improved overload protection results from "M" effect shift

higher resistance and a lower melting point than the silver alone. This permits the element to melt and separate at a current 30–35 per cent lower than would be required if the element consisted simply of silver. Since this metallurgical process requires time for its accomplishment, the time-current curves of the fuses are not affected in the high-current short-time region, but do show displacement toward lower currents in the low-current long-time region. This is evident in the melting time-current curves shown in Figure 5.

Short-Circuit Performance

With element sections adjusted to meet the foregoing specifications, and designed on the basis of the studies made after the earlier a-c and d-c short-circuit tests, acceptable short-circuit interrupting ability was demonstrated with fuses designed in standard cartridge sizes. Figure 6 shows reproductions from oscillograms taken during a-c short-circuit tests of the maximum ampere ratings in the four standard sizes: 30, 60, 100, and 200 amperes.

These records and many similar ones taken at different available short-circuit currents and angles of inception, fully substantiate an interrupting rating of 80,000 symmetrical or 120,000 total rms amperes. (See Appendix I). The records also furnish information useful in making applications. The extent of the current-limiting effect as a function of the ampere rating and the available short-circuit current can be obtained simply by measurement of the peak values of current passed, Figure 6. These, plotted as a function of available current for each ampere rating, give the current-limiting curves of Figure 7. Such test results as are shown in the current traces of Figure 6 form the "anchor points" of the current-limiting curves of Figure 7, and were checked and "smoothed" by calculation.[9] These maximum currents and their effective values and durations passed by given ampere ratings of fuses at available short circuit currents of interest establish the short-time capacities required by series connected devices. Examples are: contactor coils (magnetic stress), the contacts themselves (thermal duty), switch contacts, connections, and other fuses or interrupters in co-ordinated protective schemes. Thus the arcing time and current along with the melting time and peak currents already mentioned, are of importance in making applications.

"Let-Through" Current

Melting

As a measure of the current and time passed by a fuse in interrupting a fault, the heating effect or $\int i^2 dt$ during both the melting and arcing periods should be evaluated. In the records of Figure 6, the clear time current areas are taken as melting periods, and the subsequent time current areas (cross hatched) as arcing. Calculations indicate that the elements had sufficient heat developed in them by the passage of current to reach the melting point considerably before the times of the peak currents appearing on the oscillograms. This phenomenon was found to occur only with very high short-circuit currents, the peak currents and times for moderate available currents correspond-

ing more closely to calculated values for melting. This indicates that current continues to rise following melting on high available short-circuit current, until sufficient arc resistance has developed to cause the substantial reduction in current characteristic of the operation of current limiting fuses.

With the available short-circuit current known as a function of time, a complete description of the instantaneous current versus time leading up to melting can be calculated. However, a disparity between this mathematical description of the current during the melting period and the actual current is evident in the current traces of Figure 6. The slope of the available current is not followed by the actual current, but is reduced by the resistance of the fuse. This effect is more evident in the case of the lower current ratings which have higher resistance. Assignment of melting time and current in the short-circuit tests of Figure 6 was made using the slope of the actual current measured from the oscillograms rather than the slope of the theoretically available current.

Arcing

While current prior to melting depends almost entirely on the circuit constants and the character of the fault, the arc current following melting is influenced chiefly by the fuse, that is, by the shape of the arc voltage it produces. Although the shape and duration of arc current can be constructed by assuming values of arc voltage,[9] factual data on arc current can be obtained directly from oscillograms such as those of Figure 6. Arcing times are readily measured, and when added to the melting times for given ampere ratings, give the total clearing curves appearing as dashed lines at the bottom (high-current-fast-time) ends of the

Table IV. Current-Time Passed by High-Interrupting Capacity Fuses on High Available Short-Circuit Currents of Figure 6, and Heating Effect on Connected Wire

Ampere Rating	Melting $\int i^2dt$	+	Arcing $\int i^2dt$	=	"Let-through" $\int i^2dt$	Temperature Rise—C° Wire No.	Rise	Wire No.	Rise

200	130,000		1,190,000		1,320,000	200,000 cm.	1.2°	0	4.3°

curves of Figure 5. The arcing $\int i^2dt$ can readily be evaluated provided the current has some simple form.

If arc current falls linearly from a value i_a to zero during a time Δt, it can be shown that $\int i^2dt = i_a^2\ \Delta t/3$. More generally, if the arc current falls linearly from a value i_a to a value i_b during a time interval of Δt, it can be shown that

$$\int i^2dt = \frac{\Delta t}{3}\{i_a^2 + i_a i_b + i_b^2\} \qquad (1)$$

By use of this expression, with time and current values measured from the oscillograms, the arcing $\int i^2dt$ was computed for the tests of Figure 6. These values (in ampere-squared-seconds) are listed in Table IV, together with $\int i^2dt$ required to cause melting on a short-time no-heat-loss basis. Their sum gives the total "let-through" current-time passed by each ampere rating in interrupting a large short-circuit current.

This "let-through" $\int i^2dt$ must be tolerated by all devices connected in series with a given fuse. Depending on the resistance of the device, heat will be developed in it, and a rise in temperature will result. As a measure of the short-circuit protection afforded wire sizes commonly used with these ampere ratings in making motor branch circuit connections, the temperature rises resulting from the passage of the "let-through" $\int i^2dt$ were computed and are included in Table IV. These were calculated assuming no heat loss from the wire to its surrounding insulation during the short time interval of the "let-through."

Another use that can be made of these melting and arcing $\int i^2dt$ values is the determination of suitable ampere ratings to use in co-ordinated protective schemes. In addition to choosing ratings so that the desired sequence operation is assured in the range of times in which co-ordination schemes are usually laid out (0.1 to 200 seconds), see Figure 5, it must also be ascertained whether the "protecting" fuse can complete the work of interrupting the circuit without damaging the element of the "protected" fuse through the range of available short-circuit current involved in the application. This in turn requires that the $\int i^2dt$ passed by the "protecting" fuse in both melting and arcing shall be less than the $\int i^2dt$ required to melt the "protected" fuse.

Calculations similar to those on which were based the $\int i^2dt$ values appearing in Table IV were carried through to obtain the melting, arcing, and total $\int i^2dt$ at several levels of available short-circuit current for all the ampere ratings appearing in time-current curves of Figure 5.

Fuse-to-fuse Co-ordination

Comparisons of the resulting values yielded Table V in which are listed the minimum ampere ratings to "back-up" the ampere ratings listed in the first column. The $\int i^2dt$ values and Table V are all based on 60-cycle circuits.

The ratings listed in Table V show that successive ampere ratings should not be used in series if selective operation is desired, except in a few cases with low available fault current. The more general case requires a ratio of 2 to 1 between the ampere ratings of "protected" and "protecting" fuses, and an even greater ratio with high short-circuit currents above 50,000-amperes rms.

The same general method of comparing $\int i^2dt$ values can be used in many application problems concerned with short-time ratings of devices to be used in series with the fuses, and the application should be checked on this basis as well as with respect to sequence functioning.

Overload Interruption

Close attention to the factors making for good short-circuit interrupting ability can lead to an element design which may or may not be inherently capable of interrupting the circuit safely in the event of an overload condition. In view of this a series of overload tests were made at 60 cycles on the "final designs" of each rating with the results shown in Table VI. Some of these tests were made outdoors in cold weather, and durations in these cases were longer than those given by the melting time-current curves of Figure 5.

In these tests, particularly those in which the duration was more than ten minutes, all parts of the fuse had had ample time to assume temperatures substantially as high as those obtainable at any value of overload current. With somewhat higher current, the duration is less and the fuse does not have time to get up to temperatures as high as the empirical optimum at 150–160 per cent of the ampere rating. At less current, although the duration is longer, the wattage developed is less, and the fuse parts do not reach temperatures as high. The tests of Table VI cover the region from 146 to 204 per cent of rated current with most tests in the 150–160 per cent region producing maximum temperature rises.

Transient Recovery Voltage

Figure 8. Cutaway and section of new 600-volt 100-ampere high interrupting capacity cartridge fuse

an increasing resistance during arcing, causes a radical increase in the voltage drop across the fuse after peak current. During approximately the next 500 microseconds the voltage as measured across the fuse rises, reaching its crest at a time when current has been reduced substantially from its peak value, in many cases by as much as 50 per cent. This relatively slow development of arc resistance and arc voltage results in a relatively lower peak voltage for these low-voltage fuses as compared to voltage peaks obtained with high-voltage current limiting fuses, in which the arc resistance is caused to develop more rapidly, producing a voltage peak while current is still practically at its peak value.[11] Peak voltage values measured from the traces of Figure 6, which are typical of records of many similar tests, average to 1,190 volts, bearing a ratio to the crest of 600 volts of only 1.4. For present fuses ratio is 2 to 3.

Line of Low-Voltage Power Fuses

Figure 8 shows the construction of a typical rating of the new line of fuses designed according to the experience gained in the short-circuit and other tests described above, and to comply with the requirements of the Standard for Fuses. The 600-volt ratings of the four standard sizes, 30, 60, 100, and 200 amperes, are shown in Figure 9. While having the limiting dimensions of standard cartridge fuses, the mechanical design includes certain features which make possible the use of special clips which will not accept fuses of lesser interrupting capacity. These features consist of grooves in the ferrules of the ferrule-type ratings, see Figure 9, and a shorter body in conjunction with a projection at the base of the blade in the blade-type ratings.

Conclusions

1. The need in the United States for fuses with high interrupting capacity for use on low-voltage circuits, now can be satisfied with specially-designed fuses of the current-limiting type.

2. A line of such fuses has been developed satisfying in every respect the Standard for Fuses of the Underwriters' Laboratories, Inc.

A. Through compliance with standardized dimensions, fuses of the new line have the same physical sizes as conventional cartridge fuses.

B. Through compliance with heating and melting requirements of the Standard for Fuses, ratings of the new line provide proved overload protection, and can therefore be applied, rating for (ampere) rating in the same way as conventional cartridge fuses.

3. Interrupting ability in excess of 100,000-amperes rms at 250 and 600 volts, 60 cycles, results from use of special materials and design factors established in controlled a-c and d-c short-circuit tests.

4. D-c interrupting ability, not completely determined through the range of rates of rise of current (inversely proportional to circuit inductance) occurring in d-c circuits, also has been demonstrated to be a considerable advance over the d-c interrupting capacities provided heretofore.

5. Measurements from oscillograms taken during short-circuit tests make possible the evaluation of the heating effect, $\int i^2 dt$ of current-time "let-through" by the fuse.

6. Determination of the melting and arcing portions of the total "let-through" forms a basis for matching short-time ratings of other devices with the short-time fuse characteristics.

Figure 9. Representative 600-volt ratings of new high interrupting capacity low-voltage power fuses

Figure 10. Numerical relations between peak and rms values of a-c short-circuit currents having both a-c and d-c components

7. Co-ordinated protective schemes in which members of such a series of current ratings of high interrupting capacity fuses are applied one ahead of (nearer the source) another, call for the use of ampere ratings having a ratio of 2 to 1 or greater for large available short-circuit currents.

8. The transient recovery voltage associated with the current limiting character of such a line of fuses, is relatively slow-rising and reaches peaks in the order of only 1,200-1,400 volts, easily tolerated by the insulation ordinarily used in 250- and 600-volt circuits, and an improvement in this respect also over voltage transients produced by conventional cartridge fuses.

Appendix I

Shown in Figure 10 are the numerical relationships between the rms value of a symmetrical a-c short-circuit current, taken as 1.0, and the offset current resulting from various amounts of a d-c component added to the alternating current. In addition to the theoretical maximum of direct-current present to the same amount as the peak value of alternating current, ($\sqrt{2}$), with total rms value 1.732, well accepted[13] factors of 1.6 for transmission circuits (momentary rating for circuit breakers—also total rms current for power fuses) and 1.25 for low-voltage circuits are shown. In the latter case the maximum rms current possible in one phase would be 1.5 compared to the rms value of the alternating current alone of 1.0, the 1.25 factor being the results of averaging three phases. The ratio of peak value to the total rms (1.68 for low-voltage circuits) was used in plotting the current-limiting curves of Figure 7, in which the curve for each ampere rating becomes tangent to the line starting at 1,680 peak amperes for the 1,000-rms ampere short circuit,

and increasing linearly with the available current. The currents at which the current-limiting curves depart from this line are those at which the current limiting effect commences.

Discussion

R. H. Kaufmann (General Electric Company, Schenectady, N. Y.): The new high-speed current limiting low-voltage fuse with an a-c interrupting rating of 100,000 amperes as reported by Mr. Schuck fills a long felt want. Among industrial plants, commercial buildings, and small shops fed from low-voltage city networks, there is an extensive field for application in which the available fault current levels range from 20,000 to 75,000 amperes. It now becomes possible to apply fuse interrupters for low-voltage branch circuit protection on a sound engineering basis.

The new fuse unit alone, however, is not the complete solution. An essential associated auxiliary is a line switching unit which serves to make and break circuit normal currents (below the fuse protective level) and also allows the fuse assembly to be de-energized for fuse replacement.

The requirements for a safe switching device are quite exacting. During fuse operation, the current surge should not weld the switching contacts. Neither should a flash occur at the switch contacts which could ignite an unrestricted fault arc ahead of the protective fuses with disastrous consequences. These requirements apply whether the switch is in the fully closed position or is being closed on a faulted circuit. The switching unit must also be capable of interrupting any current magnitude below that which will produce prompt automatic interruption by the fuse unit.

The fuse clip design also is an important consideration. An arc flash could ignite an unrestricted fault arc at the source terminals of the fuse unit with disastrous results.

The crest magnitude of current passed by the fuse increases as the available fault becomes greater as illustrated in Figure 7. It is entirely possible that a particular switch and fuse clip construction may show signs of distress at an available current somewhat in excess of 50,000 amperes. The permissible interrupting rating which could be assigned to that combination fuse assembly would be limited to 50,000 amperes even though the fuse unit itself is rated 100,000 amperes.

The behavior pattern of pressure contacts in the presence of large short time current impulses is not sufficiently understood to be able to predict the performance with any degree of certainty. Only by full scale testing can the actual ability of combination equipments be established. Co-ordination testing is already in progress which will form the basis for legitimate interrupting ratings on composite equipment incorporating the new fuse unit.

N. L. Hadley (General Electric Company, Schenectady, N. Y.): While it has been generally assumed that better interrupting performance was inherently possible in the National Electrical Code dimensions, the problem has not seemed to be an easy one to solve. Some earlier work, and particularly the fundamental work by the British engineers, has shown that the behavior of even a simple fuse configuration during interruption is a very complicated process affected by many variables. It is therefore satisfying to observe that an engineering type of treatment was applied and has so well succeeded in radically improving the interrupting ability of the cartridge fuse.

This class of fuse should be useful in industrial low-voltage distributions where it will assist in obtaining a continuity of protection and application practice more nearly consistent with the rules and objectives employed in the higher voltage parts of systems. Perhaps the most difficult problem in the secondary distribution has been the selection of a device for protecting small circuits and devices in a high capacity system. The unsatisfied requirement was not simply one of economics, but was a real need for a fast low energy interrupter capable of protecting loads in addition to the supply.

C. L. Schuck: It is gratifying to note from Mr. Kaufmann's discussion that joint short-circuit testing of the new high-interrupting capacity fuses with contactors and other line switching devices is already in progress. The position assumed by the new fuse in the low-voltage protective field will be determined in large measure by the results of such tests translated into recommendations for proper application.

With regard to Mr. Hadley's comment on the need for a fuse with improved interrupting capacity, some further explanation of the data given in Table I is in order. The short-circuit current values listed describe "worst" rather than "average" performances by the lots of fuses tested, and it is felt that interest should center in such values in a subject like circuit protection where reliability and safety are issues. These tests, and all short-circuit tests referred to in the body of the paper, were made single phase, with full line-to-line voltage across a single fuse unit. In many cases, when conventional cartridge fuses have been called upon to clear faults on 3-phase systems, they have afforded protection and interrupted without disturbance, being aided by the fact that the duty was divided, the fuses in two of the three phases being effectively in series. While this favorable situation can exist for certain types of faults, there is no assurance that it will, and good engineering practice demands that an essentially single phase interruptor such as a fuse be capable of clearing faults under the most severe conditions possible.

Modern Carrier Current Test Equipment and Its Application

R. L. BRINTON
ASSOCIATE AIEE

DURING the past 20 years the carrier system of the Pacific Gas and Electric Company has advanced from two simple carrier circuits serving a total of seven terminals to the present complex system consisting of 45 circuits serving nearly 100 terminals. Originally the carrier system provided only telephone service. At present, in addition to the greatly expanded telephone facilities, the system includes relay carriers, telemetering, and remote alarm systems.

The carrier transmitting and receiving equipment now in use as a whole is not uniform in type or design. Some installations employ simple amplitude modulation and transmit the carrier and both sidebands, while other installations transmit only one sideband and suppress the carrier. Also, there are installations using frequency modulation. The power output of the transmitting equipment varies from 100 watts for the long-haul power line carriers down to 0.05 watt for the short-haul telephone line carriers.

When the carrier system was simple and consisted of only a few circuits, conventional vacuum-tube voltmeters and a cathode-ray oscilloscope were adequate as the principal tools for most maintenance and installation problems. As the equipment became more complex and the number of carrier channels on each metallic circuit were increased, the simple vacuum-tube voltmeter and the oscilloscope became entirely inadequate. Most power line carriers have a test meter panel that enables the attendant to read jack currents of the various tubes in the transmitting and receiving equipment. This method of trouble shooting is relatively slow and cannot be conducted effectively by the average substation operator. Moreover, the fault, except when it happens to be a bad tube which can be readily corrected by simply changing all the tubes in the equipment, is frequently in external apparatus of the carrier such as filters, couplers, or line trouble. Installing and maintaining this apparatus requires special test equipment such as tunable voltmeters and carrier-frequency oscillators. For example, at one major substation there are now more than 15 carrier frequencies that can be detected by a conventional vacuum-tube voltmeter connected across a tuning unit.

Several test and maintenance instruments have been developed to meet the needs of the carrier system of the Pacific Gas and Electric Company and most of these are finding wide acceptance and usage among other power utilities and the communication companies as well. For use as a signal source and for frequency determinations, an oscillator capable of delivering 5 watts in the frequency range from 20 cycles per second to 200 kc per second has been found invaluable. This instrument, referred to as the carrier frequency oscillator, provides both balanced and unbalanced output with provisions for matching impedances of 50, 200, 500, and 5,000 ohms. It will be noted from the block diagram of the oscillator shown in Figure 1 that the instrument also contains a modulator for voice frequency modulation of the oscillator output from an external source. A portable magneto telephone can be used to modulate the oscillator, thus producing a voice-modulated carrier for direct insertion on to the metallic circuits. An output level indicator, consisting of a vacuum-tube voltmeter connected across the 500-ohm output winding of the matching transformer, is included in the design. The oscillator, shown at the right in Figure 4, is a relatively small instrument, readily portable, and operates from 115 volts, 60 cycles.

A new carrier frequency oscillator now is being developed that will be similar to the one just mentioned except that the frequency range will cover from 50 cycles per second to 500 kc per second.

For measurement purposes, a carrier frequency voltmeter (designated model *101*) has been designed and manufactured to measure voltages at any selected frequency in the range from 20 kc to 500 kc. The instrument is actually a radio receiver with the d-c output from the final detector operating an indicating meter on the front panel, calibrated to show the values of the voltages applied to the input terminals. The voltmeter operates with a fixed gain and is therefore a voltage measuring device at the frequency to which it is tuned.

A telephone jack is provided on the front panel for use of a headset, to listen to incoming signals. The headset is energized from an audio amplifier, the audio level of which is adjustable from a front panel level control.

A block diagram is included, Figure 2, to explain the functions of the voltmeter. As shown, the signal input first passes through a section which includes the variable attenuator and an input filter, before arriving at the grid of the first detector. The input filter is of the band pass variety with a pass band from 20 kc to 500 kc. The variable attenuator reduces in ten decibel steps the signal arriving at the grid of the first detector so as to increase the voltage measuring range of the instrument and make possible the measurement of relatively large voltages. As shown, the steps of the attenuator between +40 and +10 are connected ahead of the band pass filter and those between −60 and +10 follow the filter.

Paper 49-211, recommended by the AIEE Carrier Current Committee and approved by the AIEE Technical Program Committee for presentation at the Pacific General Meeting, San Francisco, Calif., August 23–26, 1949, and at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted May 27, 1949; made available for printing April 26, 1950.

R. L. BRINTON is with the Pacific Gas and Electric Company, San Francisco, Calif.

Figure 1. Block diagram of carrier frequency oscillator

The tuning dial on the front of the voltmeter controls the frequency of a variable frequency oscillator over a range of 1,000 kc to 1,480 kc. The output of this oscillator combines with the incoming signal in the first detector to produce an intermediate frequency (I.F.) of 1,500 kc.

Likewise, the 1,500-kc signal, after passing through the I.F. amplifier, combines in the second detector with the 1,675-kc crystal controlled oscillator frequency to produce a second intermediate frequency of 175 kc. The output of the 175-kc amplifier goes directly into the diode detector, the d-c output of which operates the indicating meter.

An injection oscillator, which operates at 100 kc, is included in the voltmeter. This oscillator provides a fixed known amplitude signal of 0.77 volt rms (1 milliwatt into 600 ohms or 0 decibels) which can be switched to the input circuit and substituted for the incoming signal for calibration purposes. The injection oscillator circuit contains a vacuum-tube voltmeter, which can be switched to the output meter, for monitoring the amplitude of oscillations to insure an accurate injection signal amplitude. The harmonics of this oscillator provides a means for checking the frequency calibration of the main tuning dial at the 200-, 300-, and 400-kc points on the dial.

The voltmeter also can be calibrated externally by substitution of a signal frequency in the region of the frequency under measurement. The sensitivity control is adjusted by means of a control on the front panel marked I.F. gain.

The voltage measuring range of the voltmeter is from 77 microvolts to 77 volts, or 80 decibels below to 40 decibels above zero level (one milliwatt into 600 ohms). The indicating meter on the front has a 0–200-microampere range, but the scale is calibrated in decibels. The calibrations indicate in decibels the ratios of voltages at the input terminals to the receiver.

The voltmeter has sharp tuning characteristics. The selectivity characteristics of the model *101* are approximately 6 decibels down at 1 kc off resonance, 18 decibels down at 3 kc off resonance, and 40 decibels at 4 kc off resonance. The input impedance is 10,000 ohms in the rejection band and 20,000 ohms in the pass band between 20 kc and 500 kc.

A second model carrier frequency voltmeter (designated model *103*) has been manufactured to measure voltages at any selected frequency in the range from 3 kc to 40 kc. In other respects, this model is similar to the model *101*, except that it has provision for reception of suppressed carrier transmission.

As shown in block diagram, Figure 3, the tuning dial controls the frequency of a variable frequency oscillator over a range of 85 kc to 122 kc. The output of this

Figure 2. Block diagram of carrier frequency voltmeter model 101

Figure 3. Block diagram of carrier frequency voltmeter model 103

oscillator combines with the incoming signal in the balanced mixer to produce an intermediate frequency of 82 kc. The output of the 82-kc I.F. amplifier goes directly into the detector. The calibration injection oscillator operates at 10 kc and provides an output of 0.77 volt or 0 decibel. The harmonics of this oscillator also provide a means for checking the frequency calibration of the main tuning dial at the 20-, 30-, and 40-kc points on the dial.

In order to make voice transmission intelligible while using the headset for monitoring suppressed carrier transmission, the voltmeter is equipped with a carrier injection oscillator which replaces the suppressed carrier in the incoming signals. This oscillator operates on 41 kc, and provides a strong second harmonic at 82 kc which is injected into the second stage of the I.F. amplifier. Two listening jacks are provided for use of a headset to listen to incoming signals. One of the two jacks is intended for listening to ordinary amplitude modulated signals, the other for listening to suppressed carrier signals which has the carrier replaced.

The measuring range of the model *103* voltmeter also is 77 microvolts to 77 volts with the selectivity 10 decibels down at 1 kc off resonance, 21 decibels down at 2 kc off resonance, and 50 decibels down at 4 kc off resonance.

A third instrument frequently used in testing and maintenance is an untuned vacuum-tube voltmeter with special built-in features to meet the particular needs of the system. This instrument consists of a standard vacuum-tube voltmeter to which is added a set of terminals for connection to a cathode-ray oscilloscope. The signals are amplified in the vacuum-tube voltmeter circuit, thus making it possible to view relatively weak signals. A telephone jack also is included in the instrument for use of a standard headset to enable the user to make audible inspection. This instrument has a high input impedance and is principally useful for monitoring audio frequencies without upsetting the balance of the hybrid circuits.

Other test equipment of a less specialized nature, used in the maintenance of the carrier systems, are frequency meters, standard tube testers, and volt-ohmmeters. These instruments, with the specialized equipment just mentioned, make it possible for carrier maintenance personnel to maintain communication circuits and equipment in good working order and make routine performance checks so that incipient troubles can be located before actual failures occur. These facilities have materially aided in maintaining a degree of performance of the carrier systems not otherwise possible prior to the availability of these test instruments.

The carrier-frequency spectrum now is so congested that each carrier and its associated equipment should be tuned to within a hundred cycles of its assigned frequency, otherwise adjacent channel interference may result. At the present time there are no frequency meters on the market that cover the carrier-frequency spectrum. Carrier-frequency oscillators now in production are not sufficiently stable to be used for tuning line traps, tuning units, and carrier transmitters and receivers.

The Pacific Gas and Electric Company has purchased a number of army-type *BC-221* and navy-type *LM* frequency meters from war surplus stores. These particular models are the type that can be tuned to frequencies as low as 125 kc, consequently when tuning equipment on frequencies below 125 kc it is customary to heterodyne a second or third harmonic of the carrier-frequency oscillator against the *LM* or *BC-221* frequency meter.

Another test equipment problem that may arise in the near future is the need for a field strength meter to measure radiation of power line carrier circuits. The design of a new instrument, to be known as the very Low Frequency Field Intensity Meter, has just been completed for the United States Navy. This instrument is a highly sensitive low-frequency radio receiver operating as a selective radio frequency voltmeter over the 14- to 250-kc portion of the radio spectrum. It is capable of accurately measuring field intensities from one microvolt per meter to one volt per meter, depending on the antenna used. This equipment will be available commercially within a few months under the type number *NM-10A*.

The general procedure for the installation of new carrier equipment requires that extensive tests be performed on the proposed metallic circuit to determine its characteristics and to predict the performance requirements of the new installation. In making the tests it is common practice to use the carrier frequency oscillator as a carrier transmitter at one end of the circuit and the carrier frequency voltmeter as a receiver at the opposite end. The modulation features of the oscillator make it possible for the engineers to communicate between terminals during tests, which simplifies the procedure and permits more rapid progress. Usually the frequency characteristics of the circuit do not follow predictions, some frequencies showing greater or less attenuation than expected. These variations may be due to a number of causes, the most usual being the effects of branch circuits. Noise levels, also often surprisingly high, are easily measured and are usually due to cross-coupling with other lines bearing carrier communica-

Figure 4. Carrier frequency voltmeter (left) and carrier frequency oscillator (right) connected for testing power line carrier current equipment

tions, or pick-up from radio transmitting stations. All of this information is usually necessary before installation and successful operation of new circuits.

A carrier frequency oscillator, a vacuum-tube voltmeter, and a frequency meter normally are required to tune line traps. The oscillator furnishes the signal for the trap tuning but is frequently calibrated against the frequency meter in order to eliminate any error due to temperature drift. This same equipment also is used for tuning carrier transmitters.

A carrier frequency voltmeter is required to adjust line tuning units. A signal is fed into the tuning unit from either the carrier transmitter or test oscillator. Resonance of the circuit can be determined by inserting a small piece of resistance wire of about one ohm in series with each leg of the line tuning unit, and connecting the carrier frequency voltmeter across the resistance.

In the application of the test equipment to correction of faulty carrier circuit operation, it is usual for the maintenance man to first examine the condition at the nearest circuit terminus. By connecting the carrier frequency voltmeter across the circuit terminals and tuning to the frequency of the local transmitter, he is able to check the output level and modulation. Tuning to the frequency of the remote transmitter enables him to obtain the same information relative to the signal arriving from the opposite terminus. A similar use of the carrier frequency oscillator connected across the terminals will indicate if the receiver at each terminus is functioning properly In case it is necessary for the maintenance man to communicate with the opposite end of the circuit, the features of the test equipment which enable their use for communication purposes will serve his needs.

All of the test equipment has been designed to be compact and easily portable in an automobile. This makes it possible for a maintenance man to take his equipment into the field where he can readily locate troubles which cannot otherwise be isolated. The carrier frequency voltmeter can be connected directly to an open wire line and tuned to the carrier frequencies in question. The relative amplitudes of the signals arriving from the opposite directions on the circuit enable the maintenance man to determine his location with respect to a fault and indicate the direction in which to make further tests. If necessary he also can connect the carrier frequency oscillator onto the circuit and establish communication.

During field operations the test equipment is powered from a vibrator-type inverter connected to the automobile battery.

The volt-ampere capacity of any of the equipment is small enough to be powered from standard-type inverters.

During the past 20 years much advancement has been made in the design of carrier current communication system. However, little, if any, advancement has been made in the design of specialized test equipment for carrier current equipment until the last two years. Power companies and communication companies now are relying on carrier current equipment for dependable communication circuits and for other equally important functions. In order to provide these dependable circuits it is essential that suitable test equipment, such as the carrier frequency oscillator, carrier frequency voltmeter, the special vacuum-tube voltmeter, and the other test equipment described here be available to carrier engineers and maintenance personnel.

The Choice of Main Power Transformers for Generating Stations

N. E. DILLOW
MEMBER AIEE

J. W. BUTLER
FELLOW AIEE

Synopsis: In the past few years some lack of confidence has existed when the engineer is confronted with the task of specifying the main power transformer at generating stations. The proper choice of rating—cooling method, kilovolt-ampere size, voltage, insulation, and so forth—requires an approach which can be rationalized as good engineering. This necessitates not only an economic choice but one based on adequacy of electrical and mechanical requirements. It is the purpose of this paper to present an approach whereby the factors that affect the selection of main power transformers at generating stations may be evaluated.

IN THE early days of power plant projects, the selection of the main power transformer was a comparatively simple procedure. Generating units were generally small and being air-cooled had only one rating. In the power transformer the engineer had little to choose from in the methods of cooling, voltages, and size in kilovolt-amperes. At that time almost any choice would be a satisfactory one as the generating units were small, transmission voltages were low, and fuel and labor costs were at a considerably lower level than they are today.

However, at the present time the engineer is faced with at least six practical methods of transformer cooling. The transformers may be single- or 3-phase, and the kilovolt-ampere size should be suitable to match the generator rating. Transmission voltages as high as 360 kv are being considered. In addition, there is some latitude in the choice of impedance. These and other factors affect the selection of the main power transformer and will be considered so as to develop an approach to effect a proper application of the transformer.

Paper 50-128, recommended by the AIEE Transformers Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 14, 1950; made available for printing April 6, 1950.

N. E. DILLOW is with the General Electric Company, Schenectady, N. Y.; J. W. BUTLER is with the General Electric Company, Pittsfield, Mass.

Types of Transformer Cooling

The types of cooling now available are as follows:

1. Type *OA*, self-cooled.
2. Type *OW*, water-cooled.
3. Type *OA/FA*, self-cooled/forced-air-cooled. This type of unit has 100 per cent self-cooled rating and a continuous rating of 125 per cent obtained with small fans (low-velocity air) according to present standards (125 per cent is applicable to transformers rated 3,333 kva and above).
4. Type *OA/FA/FA*, self-cooled/forced-air-cooled. This type of unit, now referred to as the super-fan-cooled transformer, has 100 per cent self-cooled rating and continuous ratings of 125 per cent and 167 per cent by the use of two sets of large fans (high-velocity air). The fans are arranged and so controlled from a winding temperature relay that they are operated in two successive steps to produce the two air-cooled ratings. As an alternate approach, certain manufacturers offer forced-oil circulation to obtain one of the upper ratings resulting in a designation of type *OA/FA/FOA*.
5. Type *FOA*, forced-oil-air-cooled. This type of unit has no self-cooled rating. Pumps circulate the oil, and heat is removed by a number of unit air coolers mounted on the sides or ends of the tank. In general, transformers are equipped with unit coolers arranged in two groups. Operation of one of the unit cooler groups permits realization of at least 70 per cent of the rating with normal temperature rise.
6. Type *FOW*, forced-oil-water-cooled. This type of unit has no self-cooled rating. Pumps circulate the oil and heat is dissipated by external oil-water heat exchangers mounted on the sides or ends of the tank. Operation of one group of heat exchangers permits realization of at least 70 per cent of the rating with normal temperature rise.

It is of interest to note that industry standards on oil-immersed transformers state in substance that transformers of all types of cooling shall have a continuous rating with an average winding temperature rise not to exceed 55 degrees centigrade and the hottest spot temperature rise not to exceed 65 degrees centigrade.

Choice of Transformer Cooling

The choice of the method of cooling for a transformer may depend on consideration of load-cycle requirements, first cost, losses, reactance, installation cost, maintenance cost, shipping limitations, and other factors. However, in general, the choice of the type of cooling should be based on the most economical transformer, the one having the minimum total capitalized cost or minimum annual cost depending on one's point of view. This cost is composed of: first cost; capitalized loss evaluation; installation costs; and capitalized maintenance costs. For consideration in this paper, the economic approach to the choice of the type of cooling will be evaluated on the annual cost basis.

Capitalized loss evaluation is probably the most variable and elusive item associated with the choice of a transformer. Many viewpoints have been expressed with considerable variation in values. However, an approach deemed reasonable although giving a somewhat conservative loss evaluation is to assign both a demand and energy charge. The demand charge can be based on the installed cost of generation. The energy charge can be based on the incremental cost of power consisting primarily of fuel costs and incremental labor and operating costs. Other means of obtaining comparative loss evaluation may be desired by the engineer, and he should apply the capitalization method which he feels best fits the problem.

The economic approach to the choice of the type of cooling can best be illustrated by an example. For consideration, assume it is desired to choose the

Table I. Example of Economic Comparison for Choice of Type of Transformer Cooling

	Type of Cooling			
	OA-T	OA/FA-T	OA/FA/FA-T	FOA-T
Rating, kva*	82,500	66,000/82,500	49,500/82,500	82,500

transformer for use with a 60,000/66,000-kw preferred-standard turbine-generator to be installed in a conventional unit plan, that is, the generator and transformer are to be in series with no switching at the generator voltage. Further, let it be assumed the transformer maximum rating is 82,500 kva and the transmission voltage is 138 kv. Table I indicates an economic comparison of the types of cooling, this approach to the problem being one deemed rational. For this example, typical values are used for demand charge at $140 per kilowatt, energy charge at 2.5 mils per kilowatt-hour, and annual carrying charge at 10 per cent. For a particular application, one might choose other values for these charges. It is the approach and not the quantities tabulated that it is intended the example will illustrate.

A basic loading of 70,000 kva is presupposed as the usual operating level for the unit. It is the loading many operators consider reasonable for a 60,000/66,000-kw machine. This does not preclude the possibility that occasionally system conditions will make it necessary to operate the unit at higher loadings, especially during emergency conditions. But it is not considered good economics to base an evaluation on emergency or abnormal loading conditions. It appears, therefore, rational to use a basic loading for the evaluation rather than the maximum transformer rating for the generating station application.

On certain systems a considerable portion of the reactive requirements is supplied by the generators. Where this is the case, it is logical to include the reactive kilovolt-ampere loss charge against the transformer. This item in the loss evaluation, therefore, becomes an optional one, being included when the reactive capabilities of the generator are necessary for normal system operation.

The total annual transformer cost for the example considering first cost and losses is indicated in Table I. To this may be added the capitalized annual cost of installation and maintenance. The engineer may include these items upon estimating these expenditures for a given application. Hence, this example in Table I can serve as a guide for comparing the economics of the types of cooling available.

A limitation on the choice of the type of cooling exists in the lower kilovolt-ampere ratings. Forced-oil-air-cooled or forced-oil-water-cooled transformers are generally not considered economical under 30,000 kva, in either single-phase or 3-phase units. Self-cooled/forced-air-cooled transformers (type *OA/FA/FA*) are not considered economical under 10,000 kva at this time in either 3-phase or single-phase units. No lower limitation exists in the available kilovolt-ampere ratings for self-cooled (type *OA*), water-cooled (type *OW*), and self-cooled/forced-air-cooled (type *OA/FA*) transformers. The shipping limitation sets the maximum kilovolt-ampere rating for all types of cooling.

Choice of Transformer Kilovolt-Ampere Rating

The choice of the transformer size in kilovolt-amperes depends on the interpretation given to the various ratings and intended loadings in service of the boiler, turbine, generator, and transformer. Since the investment in transformer capacity is low relative to that in steam-generating equipment and turbine generators, it does not appear to be good judgment to be unnecessarily conservative in the choice of the main power-transformer size. Consideration of the problem will indicate that it appears reasonable to consider the maximum capabilities of the generator when choosing the transformer kilovolt-ampere rating. Practically all steam-turbine driven generators of 15,000 kva and above are now hydrogen-cooled and rated at 1/2-pound

Table III. Transformer Ratings for Preferred-Standard Turbine Generators

Turbine Generator Rating			Transformer Rating	
Nameplate, Kw	Air or 1/3-lb H_2, Kva	15-lb H_2, Kva	Type of Unit	Rating, Kva
20,000	23,529	27,058	OA	27,500
			OA/FA	22,000/27,500
30,000	35,294	40,588	OA	41,250
			OA/FA	33,000/41,250
			FOA*	41,250
40,000	47,058	54,117	OA/FA	44,000/55,000
			FOA	55,000
60,000	70,588	81,176	OA/FA	66,000/82,500
			FOA	82,500

* Type *FOW* could be substituted for type *FOA* in the table.

hydrogen pressure with capabilities of 115 per cent at 15-pound hydrogen pressure. Experience has indicated that selecting a transformer kilovolt-ampere size in the order of the 15-pound capability of the generator has proved to be a sound selection. It is recognized that an increasing number of installations obtain auxiliary power from the terminals of the main generator, but selection of a transformer kilovolt-ampere size on the aforementioned suggested basis results in a transformer rating which best matches the plant capabilities. Certain large generators are being designed for base ratings at a 15-pound hydrogen pressure. In these cases the transformer kilovolt-ampere rating should be selected on the basis of the maximum expected capability of the generator.

The choice of the kilovolt-ampere rating can be predicated on the economic factors previously considered. Without regard to the maximum loading requirements, the economics of the choice of kilovolt-ampere size is illustrated by the example shown in Table II. Again it is assumed it is desired to choose the transformer for use with a 60,000/66,000-kw preferred-standard turbine generator to be installed in a conventional unit plan. For comparison, a 75,000-kva type-*FOA-T* transformer is considered in relation to a 82,500-kva type-*FOA-T* unit. The form of the cost comparison is the same as that used for the comparison for choice of the type of cooling. The assumed basic loading for the generator-transformer combination is the same for both sizes of transformers. Reference to the total annual transformer cost comparison in Table II will indicate that the total cost is independent of the kilovolt-ampere size for the range considered. Furthermore, choice of the larger transformer rating will provide lower transformer reactance at the basic loading of the unit, and hence offers advantages in system regulation. With other factors evaluated, such as the lower reactance and the turbine-generator capabilities, a comparatively small increase in annual cost can generally be justified. The analysis of Table II is representative and further illustrates that the choice of a transformer kilovolt-ampere rating to match the 15-pound hydrogen-cooled kilovolt-ampere rating of the generator can be justified from an economic viewpoint.

From economic studies of preferred-standard turbine generators and the step-up power transformers in a unit scheme, it has been determined that the turbine-generator and transformer ratings and types of cooling listed in Table III are preferable. The choice of the type of cooling should be determined by an analysis as previously outlined.

The choice of a 3-phase unit or three or four single-phase units for the main power transformer is a question of customer preference. However, the old argument of better service continuity when using three or four single-phase units has largely disappeared due to the demonstrated reliability of modern power transformers. Because of the excellent service record, lower cost, lower losses, and lower exciting current of 3-phase units, and because of the greater installation expense of single-phase units, the trend of the industry is to 3-phase main power transformers.

The analyses employed in the examples illustrated by Tables I and II are equally applicable to single-phase and 3-phase units. Hence, this method of comparison can be used to evaluate 3-phase versus single-phase banks.

Table IV. Step-Up Power Transformers*

Generator Rated Voltages	Transformer Voltage Rating of Low-Voltage Winding
2,400/2,500**	2,300; 2,400
2,400/4,160Y	2,300; 2,400
2,500/4,330Y	
4,800; 5,000	4,600; 4,800
6,900	6,600
11,500	11,000
12,500	12,000
13,800	13,200
14,400	13,800

* Values in this table are from reference 1.

** Generator rated voltages under 11,500 volts are generally applied to low kilovolt-ampere rating machines. Thus in this range the transformers are generally self-cooled or self-cooled/forced-air with low velocity fans (Types OA or OA/FA).

Choice of Transformer Voltage Rating

Main power transformers at generating stations are oftentimes subject to special voltage requirements to fill all the application conditions required by the system design. These application conditions dictate the secondary-voltage (high-voltage) ratings. However, the transformer primary-voltage rating should be properly co-ordinated with the generator voltage rating. Table IV shows the voltage co-ordination established by the Edison Electric Institute and the National Electrical Manufacturers Association.[1] The turn ratio should be chosen to allow both transformer and generator to operate within their prescribed ratings as established by American Standards Association Standards. This is usually accomplished by choosing the primary voltage of the transformer approximately 5 per cent below the generator voltage rating.

Choice of Transformer Impedance

Power transformers are furnished with a range of impedance values available for choice by the engineer and usually found sufficient to fulfill all application requirements. The minimum and maximum values available for self-cooled transformers are indicated by Table VI. It is noted the ranges are divided into three

Table V. Approximate Base Price and Impedance Comparison

	92,001–161,000	14	20	12.5	19	11.5	18

* Impedance limits apply to self-cooled, water-cooled, or self-cooled/forced-air-cooled transformers at the self- or water-cooled continuous rating of the largest capacity winding. For forced-oil-cooled units, impedance limits of 150 per cent of values listed in the table apply in each case. This impedance will apply at maximum continuous kilovolt-ampere rating. Unless otherwise specified, transformers will usually be designed to have the minimum values tabulated.

groups: (1) fully insulated where the full winding is insulated for the line-to-line voltage class; (2) reduced insulation class of one step or reduced neutral insulation where the neutral end of the winding is graded to a minimum class of 15 kv; and (3) reduced insulation class and reduced neutral insulation.

For forced-oil-air-cooled or forced-oil-water-cooled transformers, the values of Table VI are increased to 150 per cent of those values. Generally, transformers are furnished for the minimum values tabulated. It should be noted that a change in impedance will result in a change in the load and no-load losses of the transformer.

Miscellaneous Application Criteria

Omission of Transformer Voltage Taps

For many years it has been the practice to request four taps on 2-winding transformers and six taps on 3-winding transformers. These are the maximum permissible number of taps manufacturers will provide without a price increase. However, in many applications of main power transformers, experience has indicated that voltage taps are not required. If all taps are omitted, a saving of 4 per cent in the base price of the transformers results. With modern analytical methods, such as the a-c network analyzer, system performance can be accurately determined in the planning stage, and as a result one does not need to specify extra taps to take care of the operating contingencies as has been past practice. If the transformer primary voltage rating was chosen in accordance with Table IV, the necessity of voltage taps is eliminated as the generator can be used to compensate for the voltage and reactive kilovolt-ampere loss in the transformer.

Reduced-Insulation Philosophy

With transformers for transmission voltages 115 kv and higher, the philosophy of reducing the insulation class at the line end and grounding the neutral directly with a still lower insulation class at the neutral end is a rational engineering trend.

This presupposes, of course, the use of lightning arresters rated for use on an effectively grounded system and connected in close shunt relation with the transformer. The reduction of the insulation class not only results in an attractive price saving, but also results in a lower reactance at the standard price.

Where stability is a problem, special low-reactance generators are sometimes specified. It can be shown that over-all low system reactance can be obtained also economically in transformers. The use of the reduced-insulation philosophy, at both line and neutral ends, is in this direction. As an example, a price and impedance comparison is shown in Table V.

This indicates a saving of approximately 25 per cent in the base price for reduced insulation class as well as a substantial reduction in impedance for both self-cooled and forced-oil-air-cooled transformers.

Concluding Example

It is of interest to note the contribution toward decreased costs of the main power transformer occasioned by use of the practices previously presented. For example, a 82,500-kva main power transformer bank for 13.8 kv/138 kv (engineered in accordance with prewar thinking) would probably have the following characteristics: four self-cooled 27,500-kva single-phase transformers, 138 kv grounded Y (138-kv insulation class), 13.2-kv primary rating (to be used with 13.8-kv generator), with at least four $2^1/_2$ per cent taps in the high-voltage winding. The total price would be $325,000.

Based on current trends in main power transformer application, a functionally equivalent transformer could have the following characteristics: one forced-oil-air-cooled 82,500-kva 3-phase transformer, 138 kv grounded Y (115-kv insulation class), 13.2-kv primary rating (to be used with 13.8-kv generator), with no taps. The total price is $143,000 and the savings are $182,000 or 56 per cent.

To this saving in price of the main power transformer should be added the smaller physical size, lower weight, and reduced installation expense of the forced-oil-cooled unit.

It is recognized that all main power-transformer applications cannot make use of all the price-reducing features considered. However, the example does indicate the spread in costs that are available. This requires the system and application engineer to consider the application in detail.

Summary

1. The choice of the main step-up power transformer for generating stations warrants a complete economic study.

2. Choice of the type of cooling can rationally be predicated on an economic analysis based on first cost and a loss evaluation.

3. Choice of the kilovolt-ampere size should match the maximum capability of the turbine generator. Generally, the transformer should be in the order of the

15-pound hydrogen-cooled kilovolt-ampere rating of the generator.

4. Choice of voltage rating should be such that the primary voltage rating is approximately 5 per cent below the generator voltage rating. Occasionally all taps can be eliminated and a price reduction realized.

5. Choice of impedance within the standard range is sufficient for most applications. Insulation requirements will determine standard impedances.

6. Reduced insulation philosophy is based on sound principles of engineering.

7. Large investment savings are possible by evaluation of the application requirements.

Discussion

Lester B. LeVesconte (Sargent and Lundy, Chicago, Ill.): The authors have given a good analysis of methods for estimating the real cost of transformers. While they have emphasized that they are illustrating the approach to the problem rather than actual values, one might be led to conclude that there is one particular type of transformer most suitable for a given application and set of conditions and that any engineer should be able to determine that type. Unfortunately, this does not seem to be the case because of an accounting reason rather than an engineering reason.

The authors stated that "Capitalized loss evaluation is probably the most variable and elusive item" and Table I of the paper is a good example to illustrate the truth of this statement and the lack of uniformity that exists in this field today, not only between companies but within companies.

As indicated in the paper, the charge for reactive-kilovolt-ampere loss is optional and often not included. Some also claim that the rating of generating stations would not be changed because of the transformer loss and no demand charge should be considered. Some consider the cost of energy only as the incremental cost of fuel and so forth, approaching the 2.5 mils per kilowatt-hour used in this paper while others include maintenance, overhead, and so forth, at a higher figure like 5 mils per kilowatt-hour. Some companies use carrying charges higher than the 10 per cent used by the authors while others use as low as $7^1/_4$ per cent. It is interesting to note the effect of just two factors, carrying charge and energy cost values given in Table I, using exactly the same transformer design and application. The resulting total annual costs on this basis are given in Table I of this discussion.

From these figures it will be noted that within the accounting limits given, the total annual cost can be figured to be anywhere from $17,525 to $41,500. In all cases the type-*FOA-T* indicates the lowest cost. But suppose that the type-*FOA-T* is ruled out of consideration for some other reason and a choice must be made between the other three types. In some cases the type-*OA/FA/FA-T* shows the lowest cost while in other cases it shows the highest cost. In some cases the type-*OA/FA-T* shows the lowest cost with less than $300.00 difference between it and the type *OA-T*. Thus the choice can depend on these accounting procedures.

From this it appears evident that while methods are available for the economic comparison of transformer types, as set forth in this paper, there is a crying need of more uniformity in the theory of evaluation of costs and losses.

Table I. Total Transformer Annual Cost Based on Table 1 of the Paper

	Type of Cooling			
	OA-T	OA/FA-T	OA/FA/FA-T	FOA-T

Selection, Design, and Operation of Power Transformers on American Gas and Electric Company System

I. W. GROSS
FELLOW AIEE

P. S. PUGH
ASSOCIATE AIEE

Synopsis: This paper discusses briefly the philosophy underlying power transformer practices on the American Gas and Electric Company system. It includes power transformers used in generating, transmission, and distribution stations. It does not include transformers generally used on distribution lines to serve residential customers, or special purpose transformers not directly associated with the transmission and distribution of power.

The size and extent of the interconnected electric system on which the transformers are used are described, and the requirements of such a system discussed. Considerations entering into the selection of transformers, their general design requirements, operation, and maintenance, including principles of loading, flexibility of use, and spare transformer practices, are amplified in considerable detail. Over-all economics are emphasized.

The power transformer is a most important piece of apparatus in modern electric power systems, being second only to the generator. It makes possible the widespread use of power. In larger sizes it is the largest, heaviest, and most costly piece of electric equipment, except for the generator. In total rated capacity it far outranks all other elements; hence it is worthy of the utmost attention in our search for construction and operating economies.

Fortunately, the present-day power transformer is a most dependable piece of electric equipment. It has become so reliable that interruptions to service because of transformer failure are rare. Notwithstanding, however, there is great need for less costly transformers that are still more reliable and require less maintenance. These are the goals we seek.

American Gas and Electric Company System

THE American Gas and Electric Company system is an outgrowth of many originally isolated systems of diverse origin and characteristics. It serves 1,100,000 customers in more than 2,000 communities. Well integrated and thoroughly interconnected with 16 neighboring systems at 36 different points, its transmission extends over an area with a population of approximately 4,000,000 people in seven states. Power is served to some of the most highly industrialized portions of the nation, albeit about one-third of its customers live in rural areas.

System-generating capacity of over 2,200,000 kw is available through transmission and subtransmission networks of various voltages, essentially all operated with solidly grounded neutrals. These diverse voltages (154-, 132-, 110-, 88-, 66-, 44-, 33-, 27-, 22-kv, as well as numerous lower voltages for distribution use) make the power transformer problem a complicated one, although some of the voltages are restricted to small areas.

System Transformer Requirements

While all transformers, regardless of specific use, present many similar basic problems, different factors are stressed depending on the specific application.

Generator Transformers

Transformers used to step up generator output to transmission voltages as a general rule will be larger units than those used for other purposes. They will be be fully loaded when initially placed in service and unlikely to be required, during their existence, to handle more load. Not only is this so, but they may have to carry that load for many consecutive hours or even months with little variation. We select such transformers with sufficient capacity for any load of which the combined boiler plant and turbo-generator unit is capable without penalizing transformer life. Our practice is to specify generator transformers larger than the generator, to provide for the inherent plant capabilities above nameplate rating. We do not believe it is good practice to overload such transformers and thereby appreciably decrease their life expectancy.

Generator step-up transformers often will have more than two transmission voltages, and sometimes a winding will be included for station auxiliary supply, if the economics of transformer design do not bar it. Such a transformer is shown in Figure 1.

Step-Down Transformers

Our usual step-down station serves a growing load. Initially we install a transformer of such size that it will not have to be replaced or supplemented before a reasonable economic period has elapsed. This transformer can take the normal increases in loads until it is no longer economic to load it further even with the benefit of auxiliary cooling. Such transformers usually do not have a sustained maximum demand for more than one or two hours a day. We take advantage of this to overload the unit during such periods. There are many rules evolved for operating transformers with overloads, but in large measure the determination of how these transformers shall be operated is one of operating judgment coupled with the advice of the designer in critical cases. Transformers, generally speaking, will readily take 20 to 25 per cent overloads daily without any apparent harm so long as such overloads do not last more than a short time.

Paper 50-129, recommended by the AIEE Transformers Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 14, 1950; made available for printing April 6, 1950.

F. A. Lane, I. W. Gross, and P. S. Pugh are all with the American Gas and Electric Service Corporation, New York, N. Y.

Figure 1. Four-winding single-phase generator transformer, 132Y/27/11/2.3-kv delta 40,000 kva, forced-oil and forced-air-cooled type

Three comprise a 120,000-kva bank; each is shipped completely assembled. The interior assembly has essentially been placed on its side, and the bushings depressed and tilted to limit over-all height. There are two sets of radiators with cooling fans, one in the foreground and the other at the opposite end of the transformer. This bank connects the 85,000-kw generator at the Twin Branch Plant of the Indiana & Michigan Electric Company to the 132-kv and 27-kv systems, and supplies auxiliary power to the generator through the 2.3-kv windings

Large units are required to step down from the transmission voltage to subtransmission and distribution voltages at load centers. Initially transformers in such stations have considerable capacity for load growth, differing in this respect from generator step-up transformers. We are careful not to make the transformer banks too large in order not to tie up too much capacity, relative to the load served, in a single unit. Our problem in this respect is much the same as that which determines the size of a generating unit. Such a station takes the place of a generating station in serving a community. In the ultimate setup of the station there will be two or more transformer banks so that the station capacity is not all in one bank. Usually this is a natural progression, since these stations tend to grow in size until a point is reached where diverse technical and economic conditions dictate additional stations to serve the area.

Barring other necessities, two winding units will be used, but just as often they will be transformers which step down to both a subtransmission and a distribution voltage, or perhaps two subtransmission voltages simultaneously. Considerable economy results by combining these functions into one transformer.

Transformers in large stations serving single industrial customers generally will be 2-winding transformers.

Our conventional distribution station utilizes 2-winding transformers of standard design. Single-phase units will range from 100 kva up to 5,000 kva, while 3-phase transformers will be rated from 300 kva up to 10,000 kva. They can be moved readily from one station to another as required; the majority can be connected for either 4-kv Y or 12-kv Y as needed.

Many transformers rated 1,000 to 10,000 kva are used for stepping down directly from 132 kv to distribution voltages or to subtransmission voltages in small load centers. These are 3-phase units, and the general setup of such a station will not be different from that stepping down from a lower voltage except that we omit 132-kv circuit breakers and fuses. A typical station of this type is shown in Figure 2. Usually a single 3-phase unit is the initial installation which may be replaced later with a larger one, or preferably supplemented by another similar unit as required to provide assurance against serious disarrangement of service in time of trouble.

Station Auxiliary Transformers

Power transformers ranging in size from 5,000 to 10,000 kva are used to supply generating station auxiliaries. With the unit system, it is our practice to carry

Figure 2. Transformer rated 1,500 kva 3-phase 132-kv Y/4-kv Y, stepping down to a distribution system

This transformer is tapped directly to the 132-kv line through motor-operated airbreak switches, without intervening circuit breaker or high-voltage fuses. Note the close coupled 109-kv lightning arrester mounted on the transformer tank

Figure 3. Three 3-phase 132Y/13.2-kv delta generator transformers at the new Philip Sporn Plant

They supply power from a 152,500-kw generator to the 132-kv system. Two units are rated 62,500 kva, and one unit 52,500 kva. Two larger transformers connect to the double-winding low-pressure generator and the smaller transformer connects to the single-winding high-pressure generator

the auxiliary load from two 3-phase transformers connected directly to the generator leads. Two units are used because our large generators have two independent windings, and load is best balanced in that way. It reduces risks and enables us to economize by the use of lower rated auxiliary switchgear. To provide an outside source while starting and stopping generating units and to meet emergencies, a 3-phase unit stepping down directly from 132 kv or other transmission voltage to either a single or two auxiliary voltages is provided. Such transformers are like those used in distribution step-down stations and have a capacity for the auxiliary requirements of a generating unit. Usually only one such unit is provided for a station.

Transformers for Synchronous Condensers

While synchronous condensers are sometimes provided with transformers that have no other function, most often they are connected to a tertiary winding on a main station transformer bank. Compensators are eliminated and switching simplified by using starting taps in the transformer winding. When it is necessary to have a tertiary winding for other reasons, sufficient capacity is provided to allow for the future installation of a synchronous condenser or static capacitors.

System Grounding

In stepping down from a higher to a lower voltage we usually prefer a Y-connected low-tension winding to establish a system ground so as to get the best

Figure 4. Railway portable transformer rated 15,000 kva temporarily installed at Carswell, W. Va., to supply a customer from our 132-kv lines while permanent facilities are being constructed

lightning protection and relay operation. Sometimes, however, this is not possible inasmuch as we need a Y connection on the high side, and the phasing of the system requires a delta connection on the low side. A grounding transformer on the low side then is used. Offsetting this, however, there is often a reduction in the cost of the main transformer by reason of the Y connection on the high side. Such situations require a rather complete study to determine which is the more economical and satisfactory arrangement. Generally speaking, where the higher voltages are concerned, we use the Y-connected high-tension winding for economy. If we do not provide the Y connection on the high voltage, we will have to use expensive potential transformers for relaying.

Inasmuch as our system neutrals are grounded for the most part, it is customary wherever possible to use high-voltage transformers with graded insulation, and thereby take advantage of economies in design, economics of lightning protection, and the best relaying practices.

Considerations in Selecting Transformers

Single-Phase and 3-Phase Units

Formerly, generator transformer banks, and large transformer banks stepping down from the transmission voltage to subtransmission voltages, were nearly always three single-phase units with a spare, because the physical size of a 3-phase transformer at that time made such a unit extremely difficult, if not impossible, to handle. Single-phase transformers, with a spare unit that may be connected in quickly, offers a very effective solution as far as reliability is concerned. The spare transformer and its appurtenances, however, involve a substantial idle investment at all times. With increased reliability and decrease in physical size of modern transformers, the 3-phase transformer offers a number of valuable advantages. A single 3-phase transformer without a spare involves a lower first cost but poses a problem when failure occurs. One effective answer is to utilize two 3-phase transformers, either one of which alone is capable of taking care of 60 to 70 per cent of the total requirements. When there are several generator units of similar characteristics and size, 3-phase transformers are used in each case with a single spare unit which is available for a number of generators even at different plants.

The transformer itself is not the sole consideration. Its connections must be considered, and often a 3-phase unit is not only most economical in first cost, but also in its leads, structures, and other associated appurtenances. The banking of single-phase transformers requires complicated connections, whereas a 3-phase transformer can be connected by simple direct leads. Where generating units have multiwindings or multigenerators, a 3-phase unit for each winding or generator is simplest and most economical. See Figure 3.

With our expanding system, the subtransmission networks are often fed by two or more step-down transformer stations. Thus, 3-phase transformers may be used so long as the loss of one unit will not cause intolerable voltage and load conditions. However, it is advisable to have a spare 3-phase transformer somewhere on the system which can be obtained in an emergency without too much delay.

The use of 3-phase transformers in distribution stations decreases the cost of the station and transformer so considerably that, except in cases of isolated stations, their use is definitely indicated.

Mobile Transformer Units

To provide spare requirements and meet emergencies, mobile transformers are available on our system. Five 3-phase transformers, complete with lightning arresters, are permanently mounted on drop center railroad cars. These units have all bushings permanently installed. Three of these units, with a capacity of 15,000 kva each, have a high-voltage winding of 132-kv Y and step down to

Figure 5. Portable station temporarily at Scio, Ohio, rated 2,500 kva 33/66-kv 2.4/4.16Y/7.2/12.47Y-kv supplying a load for which a station is being rebuilt

110-, 88-, and 66-kv Y, to 44-, 33-, 27-, and 22-kv Y or delta, and to 13.2- and 11.5-kv delta. All of these connections are made available by internal terminal boards which also allow 180-degree change in phase relationship. The other two units of 17,000-kva capacity each have high voltages of 88 kv, 66 kv, 44 kv, and 33 kv stepping down to low voltages of 44 kv, 33 kv, 27 kv, 22 kv, 13.2 kv, and 11 kv. These units, which are the result of many years' thought and discussion, were ordered in 1939. Although held up by the war, they became available in 1942. Although these mobile transformers were planned initially for emergen-

Figure 6. Generator transformer rated single-phase 40,000 kva, forced-oil- and forced-air cooled type 132Y/11 kv

Three units comprise a 120,000-kva bank. Installed at Philo plant of The Ohio Power Company in 1941, this is the first large power transformer to use forced oil and forced air cooling, and compact design. Note low head room, duplicate oil pumps and coolers, and low over-all height

Figure 7. A modern, single-phase 42,500-kva, forced-oil and forced-air-cooling type transformer

This unit is one of a bank connecting the 13.8-kv Number 2 double-winding generator at The Ohio Power Company's Tidd Plant to the 132-kv transmission system. On this unit, note close coupled lightning arresters, the compactness of the unit, and the installation of CO_2 piping for fire protection

Figure 8 (right). The same transformer as in Figure 7 during a test discharge of the CO_2 fire protection system

cies, they proved extremely useful in supplying sizeable war plant loads during the war, and in partially alleviating power-transformer shortages after the war. One of these mobile car-mounted units is shown in Figure 4.

We now are studying the possibilities of units of about 50,000 kva similarly mounted.

In order to provide quickly available capacity for distribution stations, we have on our system 11 portable stations. Each consists of a 3-phase transformer, with high-voltage airbreak switches, fuses, low-voltage oil circuit breaker, and control and protective equipment all mounted on a pneumatic-tired trailer. Each of these stations is capable of supplying power at 2.4/4-kv Y, or 7.2/12-kv Y. These have one of the following high-voltage ratings: 33/66 kv, 44 kv, 33 kv, 27/33 kv, or 22 kv. All of these are 3,000 kva except the 33/66-kv unit, which is 2,500 kva, see Figure 5. This 3,000-kva size has proved to be the largest which we can conveniently transport over the roads because of state highway regulations. We plan, however, that with progress in the art of building lightweight portable transformers, the use of 5,000- and 6,000-kva units for this purpose in the near future will be possible. Forced oil and forced air cooling is used in all of these cases to obtain lightweight and compact transformers.

These portable stations, in addition to furnishing quickly available spare capacity, also are invaluable for by-passing stations during maintenance or station changes, and for feeding unexpected load demands while permanent facilities are being constructed.

Autotransformers

Autotransformers are used wherever the ratio of transformation is between 1 and 2 and the systems to be interconnected are in phase. Autotransformers are much cheaper, smaller in size, and have lower impedance and losses than corresponding 2-winding transformers. All of our autotransformer banks are Y-connected with a delta tertiary. This tertiary winding has been used for synchronous condensers or static capacitors, subtransmission voltage supply, and generator input. The major autotransformations are from 154 to 132 kv, 132 to 110 kv, 132 to 88 kv, 132 to 66 kv, and 66 to 33 kv.

Transformer Impedances

Each combination of high- and low-voltage rating, together with the method of cooling, has a corresponding band of impedance within which the most economical transformer can be designed. For transformers stepping down to distribution voltages, an impedance at the lower limit of the economical band is selected. This facilitates the paralleling of transformer banks, when necessary, without loss of capacity. For transformers stepping down to subtransmission voltage where more than one station feeds an interconnected subtransmission system, impedances have to be selected so that the stations will divide the load in proper proportion. The transfer of large blocks of power on the transmission system complicates this problem and a thorough calculating board study of the system in these cases is made to determine the optimum impedances for the transformers. When selecting impedances for 3-winding units transforming to a subtransmission system with the tertiary winding used for a static capacitor or synchronous condenser, the impedances are selected so that the capacitance will be electrically close to the system we wish to regulate. When the subtransmission voltage is the one to be regulated, this impedance relationship falls within the natural economic design of the transformer, but when the transmission system is to be regulated, it entails special arrangement of windings with consequent higher cost, weights, and losses.

On 4-winding transformers, the equivalent impedances are determined and calculating board studies made on the effect of each system on the others. This is done with the different possible economic combinations of impedance. The proper selection and use of such a 4-winding transformer entails very close cooperation between the users, engineers, and transformer designer.

Transformer Cooling

Until about twenty years ago, our large generator step-up transformers were, in the majority of cases, water-cooled. One of the major reasons for this was to keep the physical size of the transformer down to a point where it could be handled readily. Even then, many of the large units were constructed in double-section tanks with the top section removed for shipment. Subsequent to 1930, with one exception, no water-cooled transformers have been purchased, but by 1941 developments in forced oil, forced air cooling made it possible for us to obtain a 120,000-kva generator transformer bank, the single-phase units of which were shipped completely assembled with all bushings in place. To obtain maximum reliability, the power supply for the fans and pumps is contained within the main power transformer, and is provided in duplicate so that either supply can operate all fans and pumps. The fans and pumps also are divided into two similar groups so that in case of trouble with either group, the

transformer will still carry 70 per cent load.

Other developments that contributed to the small and compact size of this unit were the use of oriented grain steel for the core, the placing of the core on its side instead of upright, and constructing the tank so that it conformed to the core very closely. Figure 6 shows the first such unit installed, and Figure 7 a later unit.

Oil-immersed self-cooled transformers, while employing the most expensive type of cooling, offer the greatest reliability and overload capacity. One of the greatest advantages of using self-cooled transformers is that if they are called upon to carry overloads in an emergency, the addition of portable high-velocity fans will increase greatly the capacity of these units. In emergencies, water often has been used directly on the cooling surfaces of a transformer to increase its capabilities. Forced-air-cooled transformers are often given additional overload capacity by changing the initial fans to higher velocity units. Each specific case requires study of the factors involved, and it is not satisfactory to follow arbitrary rules.

Our experience with applying fan cooling to self-cooled transformers and calculating the hot-spot temperature of the windings from the original heat run gives much higher permissible loads than indicated by the rule-of-thumb method set down by National Electrical Manufacturers Association standards.

Overload Provisions

While no specific requirements have been made as to the ability of transformers to carry overloads, this thought is always in the picture.

Any transformer that reaches an overload condition which cannot be relieved immediately is subjected to detailed study to determine the possibilities. Usually some expedient can be found to carry the load required. In the case of multiwinding transformers, light loading on one of the windings enables the others to carry substantial overloads.

Tap Changing Under Load

In designing larger distribution stations where bus regulation is required, we find it most economical to include low-voltage tap changing under load in 3-phase transformers where the capacity is 5,000 kva or more. In smaller size stations, it is often more economical to use a separate step-voltage regulator for bus regulation.

Fire Protection of Transformers

Special fire protection for transformers has been used only in relatively few cases. Generally speaking, these involve generator step-up transformers. In a few instances we have installed automatic sprinkler systems, using spray nozzles to extinguish the fire.

We have installed a larger number of protective schemes on generator transformers using carbon dioxide as the extinguishing agent. This has been done notably at all our most recent generating stations. In many cases fire barriers have been built between adjacent transformers when they were located in important installations. Figure 8 shows a test discharge on the transformer shown in Figure 7.

For the most part, however, special fire protective barriers and extinguishing systems have not been applied to power transformers. The fire protective and extinguishing equipment supplied for a station as a whole has been selected to be adequate for transformer fire protection. Generally speaking, it consists of water available in the form of spray, or foam supplied either through fixed or portable equipment. In the smaller transmission and distribution stations the fire protective equipment for transformers is generally no more than is available for other risks.

Transformer Design

Lighter Weight

The modern transformer is more economical in its use of material than was the case a few years ago. It is therefore lighter and has smaller dimensions than formerly. This is reflected directly both in the cost of the transformer initially and in the lower costs of installation. Less costly foundations are required, less expensive structures will suffice. The lighter weight and smaller dimensions also enable complete factory assembly so that it can be installed directly on its foundations without any appreciable assembly work. This further contributes to economy of installation.

Multiwinding Transformers

While most transformers are of the 2-winding type, it often has been found economical to utilize transformers having three or four windings, and consideration has been given to units having five windings.

As the number of windings increases, design problems become more difficult. Only in the larger size transformers is it feasible to have these extra windings because of the lack of space on the outside of the transformer to locate the various bushings and other accessories. There is a distinct saving in first cost when transformer capacity is attained by including additional windings, and an equally attractive saving in foundations, structures, and simplified switching. When any one of the windings is less than one-fourth the capacity of the largest winding, the economics of including the smaller winding should be questioned.

Transformer Taps

The mistake of not having enough transformer taps is more often made than that of having too many. In the higher voltage transformers it is customary to place a sufficient number of taps in the high-voltage winding to cover the range of voltages which is likely to be encountered. Except in rare cases, this range will not exceed 10 per cent of the rated voltage, nor will more than five taps be required. In the lower voltage and the smaller transformers, it has been necessary to consider past practice in arriving at taps and tap ranges. Many years ago most distribution systems were based on 2,200 volts, or in the higher voltages some multiple of 110 volts. Transformers customarily were purchased with a given high voltage and four or five taps at $2^1/_2$ per cent intervals below that voltage. As voltage standards increased, 2,200 volts were changed to 2,300, later to 2,400, and then to 2,500. It was necessary in buying new transformers that they parallel in

Figure 9. A single-phase unit of an autotransformer bank rated 105,000 kva, forced-oil and forced-air-cooling type

The over-all height of this transformer has been kept to a minimum by the location of the bushings in pockets on the sides of the tank and the use of a special lightning arrester composed of two separate vertical stacks connected in series

some degree, at least, the old ones. Consequently, through the years our specifications have been changed so that the new transformers would parallel at least partially with the old ones, but at the same time attempts were made to keep the tap range and the number of taps within standards which would not penalize us on first cost. Fortunately, this situation has now worked out so that the taps and tap ranges generally used by the industry are applicable to our purposes and will parallel with the older transformers without too much difficulty.

In a 2-winding transformer the tap situation is relatively simple. One winding need have no taps at all, and the other can be designed to cover the voltage range which the transformer must serve. There is usually not too much difficulty in arriving at a choice in this matter. In 3- or 4-winding transformers taps are needed in all but one of the windings to provide the same flexibility attained in 2-winding transformers.

Lightning Arrester Application

The impulse or lightning protection of transformer insulation has received serious consideration on our system for some thirty years. As field research determined the characteristics of natural lightning and laboratory work disclosed the effects of lightning on transformer insulation, and, further, as the protective characteristics of lightning arresters were better understood, it was possible to co-ordinate all factors on an engineering basis.

In the early 1930's it became apparent that lightning arresters, which in some cases previously had fallen into disrepute, were not capable of protecting the then existing transformers; the lightning-arrester protective levels were too high, and the transformer insulation strength was too low. As the result of a careful study made at that time, it was decided to reduce lightning-arrester ratings over the entire high-voltage system and this resulted in marked improvement in transformer performance against lightning surges.

The success of this forward step was followed by further study of the possibility of reducing transformer insulation below the then accepted industry standards of impulse values of full rated insulation, and co-ordinating the transformer strength with lightning-arrester protective levels was undertaken. This resulted, in 1934, in adopting the so-called reduced insulation on a 30,000-kva 132-kv transformer bank where a lightning arrester of reduced rating was mounted directly on the transformer bank; see

Figure 10. A portable tent attached to steel A frame for weather protection during field repair of a transformer

This tent and an electric hoist are portable and fit a number of different A frames, and are moved to locations as needed. The top of tent rolls back for untanking transformers

Figure 9. In this way, it was possible to use 115-kv class insulation for the transformers and a 75 per cent lightning arrester on our 132-kv grounded neutral system with an over-all saving in the order of 15 to 20 per cent. This practice has been continued up to the present time with complete transformer protection and entire satisfaction.

During the last 16 years, there have been installed on the American Gas and Electric Service Company system, nearly 3,750,000 kva of transformer capacity in the range of 88, 132, and 154 kv, all having reduced insulation, that is, one level below the standard basic impulse level values. 180,000 kva have been on 154-kv lines, over 40,000 kva on 88-kv lines, and approximately 3,500,000 kva on the 132-kv system. Practically all of this kilovolt-ampere capacity has been impulse-tested at the factory to the extent that one transformer, at least, of any bank has received the factory test, and in some cases all transformers comprising the bank. In almost all cases where reduced insulation is used in the transformer windings, bushings likewise have a reduced insulation rating. The saving in first cost of the transformers alone, to date, by the use of reduced insulation as described here, has been estimated at $1,500,000.

Commercial factory impulse tests have been a valuable and indispensable means of proving that the transformer strength specified actually is obtained. In 12 cases of transformer failures that occurred on factory tests, defects in the design or faulty workmanship or material were found in every case. To our knowledge some 500,000 kva (13 per cent) of transformers capacity-tested have failed during the factory impulse tests mentioned.

At the present time, in adapting lightning-arrester protection to transformers, all important cases are checked to make sure that the lightning arrester properly fits the application as regards providing an adequate lightning arrester (60-cycle rating), and maintaining a margin between the lightning-arrester protective level and the transformer-tested strength.

We have not carried reduced insulation into or below the 66-kv class of transformers, as no transformer cost reduction has been indicated by the manufacturers up to the present time.

In all cases where reduced transformer insulation has been applied, the system has been grounded solidly, although quite a few cases exist where the transformer is delta-connected. The system overvoltages under fault conditions, however, are such that reduced rated arresters, in the order of 75 per cent, have been applied with some 30 per cent margin or more between the lightning arrester protective level and the transformer full-wave tested strength.

Transformer Accessories

Transformer accessories, such as thermometers, oil gauges, hot spot indicators, alarm signals, tap changers, radiator valves, drain valves, explosion relief devices, fans, oil pumps and controls, trucks and nitrogen gas control equipment, do not have the same reliability and long life as the transformer windings themselves. These devices usually require more maintenance over long periods of time than the other parts of the transformer. In the last 20 years considerable improvement has been made in respect to oil gauges, valves, explosion relief devices, tap changers, and nitrogen gas control equipment, but all such accessories still require considerable maintenance and there is room for further improvement.

On large transformer banks, bushing current transformers are provided on all line bushings for operating the transformer differential protection. An extra set of bushing current transformers is also provided on the high-voltage bushings where the transformer is connected to the 132-kv system without a circuit breaker; these are used for high-speed carrier current relaying.

At small distribution stations, bushing current transformers are provided on the low-voltage bushings to operate thermal demand meters. This has proved the

least expensive method of transformer load indication.

Considerable progress has been made in preventing leaks in transformer tanks. The main steps in this direction have been the elimination of gasketed joints by welding, wherever possible, and the substitution of properly designed gasket joints using synthetic rubber instead of cork, where such joints are necessary.

Oil Preservation

Our experience through the years with the different methods of oil preservation has indicated that the use of a cushion of nitrogen gas over the oil, maintained by a bottle of nitrogen gas under pressure, is the most satisfactory. This gives maximum preservation of the oil, has less chance of rupturing the tank and causing a fire from an internal explosion, and leaves the tank cover free of obstacles such as conservators which interfere with the high-voltage lead connections.

Transformer Operation

Field Servicing of Transformers

No matter how well the transformer aspects of an electric system may have been worked out, designs perfected, overvoltage protection supplied, and construction carried out satisfactorily, there is always the problem of field maintenance after the transformer is put into use. Field servicing during the useful life of equipment is a very important element of transformer operation.

About 1932, in connection with the power-factor field testing of bushings, we started in a small way similar insulation testing of the larger power transformers. This test work has expanded steadily, and numerous conditions hazardous to safety and continuous operation of transformers have been found in this way and corrected before costly failures occurred. Field power-factor testing of large power transformer insulation is now on a routine basis. Tests are being made periodically at approximately 3-year intervals. These tests include not only transformer windings but also transformer bushings and oil. We also use a special field test set, developed by us, to determine oil neutralization number and color where the oil is questionable. In addition, dielectric tests of the oil are made at much more frequent intervals. In cases where field tests have shown the oil questionable, a detailed oil analysis is made in our laboratory and, based on our laboratory recommendations, the oil is reconditioned or reserviced as required.

Oil Handling

Over the years our ideas about the handling of oil for transformers have undergone a great change. At the present time our object is to make the facilities for handling oil as simple as possible. It is necessary to supply clean and dirty oil tanks at nearly all large stations. While formerly we used very elaborate fixed pumping systems, with large amounts of pipe laid in the ground, much of this has been eliminated. Our general practice now is to utilize portable pumping and filtering equipment which can be moved directly to the apparatus being treated and to use flexible tubing or other portable piping. This transition from the elaborate oil handling and purifying schemes of the past has resulted in a tremendous saving not only in equipment but in building space.

Reclamation of oil is carried out by filtering through fuller's earth when necessary.

Transformer Protection

All of the larger transformers have differential relay protection. Generator transformers do not have overload protection; but, generally speaking, the transformers in step-down stations do. Frequently, generator transformers will have not only a separate differential relay system but also differential relay protection to include both the generator and the transformers.

Although Buchholz relays have been used to a large degree in Europe, and we have given them serious consideration, they do not appear to us to have sufficient advantages to justify their use.

Transformers in the large sizes and especially those with forced oil, forced air cooling have been provided with thermal relays which function if operating temperatures are exceeded (which may result from loss of air or oil pressure). While some advocate tripping the transformer off the line when these relays operate, we have felt that it is preferable to use the alarm to give a warning signal only.

Switching Spare Transformers

Although it was general practice in past years to move spare transformers to replace a damaged unit, the time and effort required resulted in serious delays in restoring service. As a result of our experience we now arrange the spare transformer so that it can be cut in and out of service to replace any regular transformer without physically moving it.

In case of a delta connection, this can be done readily by using hot-line clamps to connect the spare transformer to the proper extended delta bus. For a Y connection, one terminal of the spare transformer is permanently connected to the neutral, and a jack bus extending from the other terminal permits replacing any transformer of the bank. Where two banks are used a single spare, in the same way, can serve both. Anything more elaborate than this is not warranted.

In a few isolated cases, substitution of the spare transformer for one of the others has been carried out without de-energizing the transformer bank by using hot-line tools. A great deal of care is necessary in carrying out such an operation, and except in emergencies, it is not generally recommended, although experience has proven that it can be carried out successfully.

Field Repair of Transformers

When necessary to repair transformers, serious consideration is given to whether or not the work will be done at the transformer location. Minor repairs are carried out at the site. For major repairs, the transformer is usually moved to a location where there are adequate shop facilities. Such facilities are available on the American Gas and Electric Company system at a few of the older major stations. Experience has shown, however, that these were seldom used; hence, in later stations they have not been furnished. Major transformer rebuilding or repair is best handled by transporting the transformer to the factory or manufacturer's service shop. On a system such as ours, which is spread over a very wide area, it is more economical to handle the situation in this manner than to have a central service shop requiring the maintenance of an organization and facilities.

Transformer Overhaul

It has never been possible to determine how frequently large power transformers should be given periodic overhauls. Although this subject has been studied for many years, our conclusion is that such overhaul should be undertaken only when it is indicated that the transformers need it. While it is somewhat difficult to tell just when they do need an overhaul, data obtained from Doble power-factor testing, from the use of meggers, and by testing the oil usually is sufficient to give us a clue as to overhaul requirements. An inspection without untanking sometimes will suffice.

Most field overhauling of large transformers has been carried out by the use of *A* frames and temporary shelters. At a

number of points on the system it was customary in years gone by to install permanent *A* frames, usually at large transformer stations. This is not the present practice. It is more economical to set up temporary wood pole *A* frames with canvas shelters for carrying on this work. A typical *A* frame and portable canvas shelter is shown in Figure 10.

Smaller size transformers are best moved to a point where hoisting and other facilities are available for handling that kind of work. This may be the manufacturer's service shop or a company service shop.

Summary and Conclusions

Among the highlights of our transformer practice described in this paper are the following:

1. The rating of generator transformers always exceeds the generator nameplate rating in order to take advantage of the overload capabilities of the generator.

2. By improvement of transformer iron, forced oil cooling, and the reduced insulation we use on our 132-kv system, the over-all weight, dimensions, and cost of large transformers have been basically lowered.

3. Autotransformers are used, where applicable, because of their greater efficiency and lower weight and cost, where transformation ratios do not exceed 2-to-1.

4. Three-phase transformers are now used in many locations because of decreased cost, a high degree of reliability, and because their use simplifies installation arrangements.

5. About $1,500,000 in initial transformer costs has been saved during the past 16 years by the use of reduced insulation (one level lower than industry standard) for transformers on our 132-kv system, with complete satisfaction and without a single transformer failure resulting from this practice.

6. Some transformers arranged for tap changing under load have been used, and the practice has become more prevalent. These are applied generally in the distribution range of 4 to 12 kv; so far it has not been found necessary above 44 kv.

7. The practice of using multiwinding transformers, for example, three and four windings, is quite prevalent and has resulted in considerable economies.

8. Field servicing of large transformers was formerly done on the site. At the present time, where major repairs are required, usually it is done at the manufacturer's plant or at the service shop.

9. The size and characteristics of our system require that transformer reactances, in many cases, be chosen to fit each application. In such cases, we make calculating board studies of the system setup to predetermine the required transformer reactances to produce the desired power flow under stable and transient conditions.

10. Portable railroad car mounted transformers in a high-voltage range of 33 to 132 kv now are available for use on our system. These are 15,000- to 17,000-kva 3-phase units, and have proved invaluable during and after the war to supply emergency loads and provide temporary service while new stations were being built.

11. Eleven portable substations for highway transportation, consisting of 3-phase transformers, switching, and protective equipment are in use. In general, these are 3,000 kva, with voltage ratings from 22 to 66 kv on the high side, stepping down to distribution voltages. The availability of these portable substations eliminates the necessity of providing spare transformers in many small distribution stations. They also are used to by-pass stations during repair and serve emergency loads.

Discussion

F. L. Snyder (Westinghouse Electric Corporation, Sharon, Pa.): The authors have thoroughly and concisely outlined the principles followed by the American Gas and Electric Company in the selection, design, and operation of power transformers. I would like to briefly point out the savings in capital investment in transformers which can be achieved through the medium of the principles outlined in the paper.

Assuming that the cost of four single-phase transformers for a 75,000-kva generating station and a transmission voltage of 138,000 volts is 100 per cent, or a base cost of approximately $322,000, the following reductions in capital investment can be made by taking advantage of certain principles in the design and operation of the transformers for such a station:

1. At generating stations, the use of two 3-phase transformers instead of four single-phase transformers reduces the cost $51,000, or 15 per cent.

2. The use of one 3-phase transformer instead of four single-phase transformers reduces the cost an additional $40,000, or an additional 15 per cent, or to 72 per cent of the base.

3. The use of water-cooled transformers instead of self-cooled transformers reduces the cost another $38,000, or 17 per cent, or to 60 per cent of the base.

4. The use of forced-oil cooling with an oil-to-air cooler reduces the cost an additional $30,000, or 15 per cent, or to 51 per cent of the base.

5. If an oil-to-water cooler is used instead of an oil-to-air cooler, additional savings of $14,000 to $149,000, or 47 per cent of the base, will be achieved.

6. The use of a graded insulation with full basic impulse levels makes possible a further reduction of $7,000 to $142,000.

7. Reducing the insulation level from one full voltage class achieves a further cost reduction of $15,000, or roughly 10 per cent.

8. At switching or receiving stations where, because of higher low voltage the base cost may be $381,000, the use of an autotransformer instead of a 2-winding transformer at the step-down stations on the transmission line makes possible an ultimate reduction in cost to 30 per cent of the base, assuming that the transformation ratio is 138,000 volts to 69,000 volts.

The trend towards the use of 3-phase transformers rather than single-phase transformers is illustrated by production statistics, which show that whereas 20 years ago two-thirds of all large power transformers were single-phase and only one-third 3-phase, today two-thirds of all such transformers are 3-phase and only one-third are single-phase.

Today approximately 50 per cent of all large power transformers are forced-oil cooled, approximately 25 per cent have auxiliary forced-air cooling, and approximately 25 per cent are straight self-cooled—whereas, prior to World War II, practically all large power transformers were straight self-cooled, either with or without auxiliary forced-air cooling.

It is recognized that it may not be possible nor practical to take advantage of all of these principles on any one particular installation, but it should be possible to take advantage of one or more in the great majority of large power transformer applications, as the authors have done.

Eric T. B. Gross (Illinois Institute of Technology, Chicago, Ill.): This paper should be of considerable interest to the power systems' engineer since it indicates present-day practices of a large company. Of particular value are references to previous practice, as for example the comparison between 3-phase transformers of today and banks of single-phase transformers used before the war. I am not too certain, however, that the size of the 3-phase transformer prevented its application, since I remember that 3-phase units of 75 megavolt-amperes rating were in use in Europe in 1935, and these were designed for 50 cycles.

It is noted that transformers with a nitrogen cushion above the oil level is given preference. However, it seems that the experts are not unanimous in the opinions as to the value of this method and the conservator type. In Canada, for example, conservators are used without exception,[1] and recent Swedish research seems to indi-

cate that inhibitors used with conservators preserve the oil excellently.[3]

It is interesting that bushing current transformers of the transformer proper are used for differential protection, thereby limiting the zone of protection to the inside of the tank, and excluding the leads to the circuit breakers and the outside of the transformer cover.

The statement that gas- and pressure-relays do not appear "to have sufficient advantages to justify their use" needs some qualification, especially in the light of recent experiences in Canada with such relays,[4,5,6,7] and with reference to the report on Relay Protection of Power Transformers[7] which contained the following recommendations:

"The value of gas accumulator relays for detecting incipient faults has been underestimated generally in the United States.

"Substantial experience in Canada has demonstrated the value of gas accumulator relays to detect conditions such as turn-to-turn faults, core insulation failures, and defective joints.

"Objections commonly raised to the gas accumulator method of detecting faults can be overcome largely by suitable application and proper interpretation of relay indications.

"The present commercially developed gas detector relays are limited in application to conservator-type transformers. Experimental installations indicate that devices may be developed for extending gas detection principles to other types of transformers."

"The wider application of pressure protection offers considerable promise: (a) to provide supplemental protection with sensitivity greater than usually obtained with conventional differential schemes alone; (b) for protection, when used with overcurrent relays, where it is not feasible to provide a satisfactory differential scheme; (c) to solve inherently difficult application problems, such as with step regulators and rectifier transformers; and (d) for fast, low cost protection and reclosing lockout of feeder voltage regulators."

A. N. Garin (General Electric Company, Pittsfield, Mass.): This very comprehensive paper by one of our leading utilities will undoubtedly stimulate an exchange of views and will be studied and discussed by the engineers of other operating companies. I am sure, however, that engineers of various transformer manufacturing companies will be even more interested in what amounts to a very first systematic exposition of the present ideas on transformers, by the users of transformers.

A power transformer is a wonderful piece of apparatus, with a very long and impressive history back of it. It possesses inherent flexibility, and offers great opportunities for still further development. The progress in the design and manufacturing of power transformers over the last half century has been truly extraordinary. Naturally, this progress has been directed simultaneously at quite a few somewhat divergent, but fortunately not completely irreconcilable, objectives. Modern transformers, as contrasted with their prototypes, are not only smaller, lighter, less costly, more efficient, and more reliable, but also incorporate many features that were absent in the original product. These features have been built into transformers to utilize them as (to quote a comparison that has been used before) "universal joints" in a power transmission system. I need only mention means for adjusting the turn ratio or the phase angle of transformation at no load, or without interruption of the load, various reactance relations in multiwinding transformers that fit, or complement, the reactances of the transmission system itself, and so forth.

Undoubtedly, simultaneous progress in all of these directions can continue for a long time to come. Better understanding of the fundamental electromagnetic and thermal phenomena in transformers, better materials, and better manufacturing techniques will result in transformers becoming more efficient, reliable, less costly, and smaller in weights and dimensions, and incorporating to an even greater degree various special features that make the transformer such a versatile link in the power system. It must be realized, however, that if the objectives were more clearly defined in the order of their importance, much more rapid progress could be achieved by concentrating on a few of the very many desirable characteristics.

Obviously, it is up to the operating people to define the objectives that are foremost in their mind. To quote from the paper: "There is great need for less costly transformers that are still more reliable and require less maintenance."

If we accept this statement as a directive indicating the preferred line of advance, then some general observations can be made. It must be recognized that minimum cost, maximum reliability and minimum maintenance are, of necessity, somewhat inimical to the requirement of flexibility in application. To illustrate, a design with load ratio control or manual taps permitting the operation of a transformer at a number of different transformation ratios cannot be, in the nature of things, as economical in the first cost, as reliable, or require as little maintenance as a similar transformer without taps. Similarly, a transformer with considerable overload or over-excitation capacity built into it cannot possibly show the same degree of utilization of materials in its construction as a transformer of similar rating but designed for operation at constant excitation and constant load. The oil conservator has proved itself, in the opinion of many operating companies, to be an entirely adequate method of oil preservation for modern power transformers, and yet the brief paragraph in the paper under the title Oil Preservation states a definite preference for gas cushion transformers.

It is important that purchasers of transformers realize, as transformer designers do, that a gas cushion design requires a taller tank than an oil conservator design; therefore, the preference expressed stands in conflict not only with the objective of minimum maintenance, but also with the objective of obtaining minimum weights and dimensions and maximum kilovolt-ampere ratings capable of shipment without disassembling.

This line of reasoning can be carried farther. For instance, maximum inspectability of the transformer core and coils or maximum accessibility of various parts of the transformer for repair work will, in some cases, militate against compactness and economy of design. Obviously, no academic approach can be taken in connection with such an eminently practical and vital piece of equipment as a transformer, and none of the practical requirements could be neglected or disregarded for the sake of spectacular progress in some selected characteristics. Nevertheless, it would be very helpful, both for the users and manufacturers of transformers, to give this matter of somewhat conflicting requirements more thought than perhaps has been given in the past.

The question of emphasis on some characteristics at the expense of others is particularly important when transformers for more or less special applications are under consideration. As an example, generator transformers referred to on the first page of the paper are a specific case where maximum economies, reliability, and kilovolt-ampere capacities within the limits of permissible weights and dimensions can be obtained by a clear-cut policy of limiting the number of windings to two, eliminating all the taps, and permitting a free choice of the voltage rating of the low-voltage winding, on the basis of a concept defining a step-up transformer as an integral part of the generator.

Another example along the same lines is the case of mobile units referred to in the paper. On the assumption that the two primary objectives in mobile units are obtaining maximum capacity within the limits of weights and dimensions imposed by transportation facilities, and obtaining maximum flexibility of connections to make these units suitable for application at as many points of a system as possible, it follows that some other characteristics and requirements, normally expected of stationary transformers, must be sacrificed. These characteristics may be the level of losses, the sound level, the reactance level, the insulation level, and the temperature rises. However, a reduction in insulation level might be particularly undesirable in a piece of equipment that must be relied on in emergencies.

An increase in the temperature rises may be equally unacceptable because of its bearing on the probable useful life of the equipment. Increased reactances may affect undesirably the usefulness of the portable transformer as an emergency link in the

system or may necessitate extra wide tap ranges in the windings to compensate for the high regulation drop, thus resulting in larger, rather than smaller, size and weight per kilovolt-ampere of output. It is obvious, therefore, that any sacrifice in any one of these directions may be objectionable and should be a matter of explicit consideration and complete agreement between the purchaser and the manufacturer.

Broadly speaking, we are in complete agreement with the comments on impulse testing. It cannot be stressed too much, however, that not only the value of commercial impulse testing, but the advisability itself of subjecting transformers to commercial impulse tests, depend completely on the reliabilty of failure detection. Thus, the statement: "Commercial factory impulse tests have been a valuable and indispensable means of proving that the transformer strength specified actually is obtained" is true statistically, but the possibility is not excluded that some of the transformers, particularly in the early years of impulse testing, that apparently passed the test had actually failed without the failure being detected. The next statement to the effect that: "In 12 cases of transformer failures that occurred on factory tests, defects in the design or faulty workmanship or material were found in every case," could also be amplified. The greatest concern of transformer designers and manufacturers in connection with impulse tests does not lie in the possibility that the tangible cause for failure of a given unit on impulse test will not be found, but in the possibility of damaging the transformer by the impulse test without any indication of this damage within the scope of the failure-detection means incorporated in the regular commercial testing procedure. Only the gradual advance in the art of impulse testing from this particular viewpoint and the present reliability of detection justify the widespread practice of subjecting transformers to commercial impulse tests. Engineers of the American Gas and Electric Company have always been outstandingly willing to co-operate with transformer designers in discussing the specific objectives and requirements of the more complicated transformers.

As pointed out in the paper, one example of a situation where such discussions can result in very substantial savings and improvements in quality of the product is the case of multiwinding transformers referred to in the paper. A 3-winding transformer has three values of short circuit impedance between windings, a 4-winding transformer has six, and a 5-winding has ten. A system study may indicate certain preferred values of these reactances and normally this information is passed on to the transformer manufacturer with the request that he provide a design which will satisfy all of these impedance values. Now, a transformer is a very flexible device and a good transformer designer is a very skillful manipulator of shapes, dimensions, and arrangements of windings so that usually he can arrive at a design to satisfy all of these impedance requirements within the accepted American Standards Association tolerances. It would be a miracle, however, if such a design should also give maximum economy and reliability. Very often slight departures from specified impedance values, so slight that they would not affect the usefulness of the transformer on the system, result in a much better design.

F. A. Lane: Mr. Snyder's comments add emphasis to some of the points brought out in the paper. Most of his data have to do with the first cost of the transformer. It is important, however, not to lose sight of other costs, many of which have a strong bearing on the final installed cost of the transformer, which, in the end, is the thing we are after. It may be found that the transformer which is sold at the lowest price is not the most economical one when finally installed. For example, the connections to a transformer or bank of transformers may be simple or very complex. A complex arrangement may cost a great deal of money, and whether it is simple or complex may depend on the type of transformer. It is often found that a more expensive transformer will result in a simpler connection layout and lower installed cost. Hence, while attention must be paid to the design of a transformer from the first cost angle, this should not be to the exclusion of other factors which will enter into the final installed cost and which, if not carefully surveyed, may result in a higher final cost than is warranted.

Mr. Eric T. B. Gross points out that large-size 3-phase transformers were in use in Europe at least as early as 1935. In this country we could have used larger 3-phase transformers than were used had we so desired. At that time, however, the reliability of transformers had not been as well established as it is now, and a great many large transformer banks were made up of single-phase units in order to guard against loss of transformer banks for extended periods. Spare transformers were usually immediately available in case of failure.

Mr. Gross also comments on the use of bushing current transformers in the transformer proper for differential relay protection, thereby limiting the zone of protection to the inside of the tank. This practice has not proved to be disadvantageous and it may be noted that it is inside the tank where most destructive results occur. The loss of a bushing or the loss of connections external to the transformer is not a serious matter, as these can be replaced with relative ease and at relatively low cost. Damage inside the transformer, however, is another matter and may have extremely serious consequences.

Reference is made to the use of gas relays and it may be noted that this type of relay has been known in this country for a great many years. It has been given a great deal of consideration. Many of us, however, are far from convinced that the gas relay has a great deal to offer that we cannot get some other way.

Mr. Garin brings out in his remarks the necessity for compromise in design of a transformer to meet all of the requirements. It cannot be too strongly emphasized that the best results can only be in the nature of a compromise. All angles of the problem must be studied, and frequently it is necessary to discuss the transformer itself in great degree with the manufacturer. As users we are not designers and do not have the understanding of the fine points of transformer design that are within the grasp of those whose specialty is to design and build transformers. By getting together with these people, however, and by exchanging points of view between the user and designer, it is possible to bring out the effect of various changes in design on the results which the user wishes to obtain. In this way a compromise design may often be arrived at, with more satisfactory results than would have been the case had such conference not been had. It is always helpful if all those concerned can discuss the problems involved.

Mr. E. T. B. Gross and Mr. Garin raised a question about the gas cushion transformer. It should be made clear that we do not question the ability of the conservator-type transformer to give us good results with the insulating oil. For a long time we went on the assumption that both conservator and gas cushion designs gave essentially the same protection to the oil. Accumulated experience now indicates that the gas cushion is superior in this respect.

It is pointed out that the transformer with the gas cushion has a taller tank than that of the conservator type. It might be questioned that the over-all height of the two transformers is vastly different when we get all through with them. The conservator tank has been found to interfere seriously with a proper installation of a transformer. Emphatically it is in the way. Getting leads from the various bushings so placed that clearances will be adequate has proved, time and again, to be a most embarrassing problem. Elimination of this conservator tank largely eliminates that problem. For this reason more than any other, the conservator tank has become an unwelcome portion of a transformer.

In addition, the point is often made that the conservator tank supplies a head of oil to feed the flames of fires that are started at the time of bushing failures which result in fracture, allowing oil to escape and catch fire. While this has often been the case, it may be reasonably argued that it has not taken place sufficiently often to be a major factor. However, it is a substantial one in the eyes of many users.

It may be noted that the writers of the paper feel very strongly that impulse tests of new transformers have been amply justified by the results. There has been some tendency to question this. The record, however, can speak for itself, and there is no question but that the results of impulse testing have shown the way to detect design and construction defects in transformers, and to give us a product that is highly reliable.

Thirteen-Year Lightning Performance of Boulder 287.5-Kv Transmission Lines

T. M. BLAKESLEE
FELLOW AIEE

E. L. KANOUSE
MEMBER AIEE

THIS paper presents the lightning performance data that have been accumulated on the 287,500-volt Hoover Dam-to-Los Angeles transmission lines over the first 13-year period these lines have been in operation. The design data for these circuits have been presented to the Institute[1] and a comparison with other high-voltage lines in this country on features pertinent to lightning performance will be found in an AIEE committee report presented in 1946.[2] Figure 1 shows a standard single-circuit suspension tower and indicates the dimensions pertinent to lightning performance. Figure 2 presents the general geographic layout of the three transmission circuits, their terminals, and switching stations.

The line passes from cultivated land around Los Angeles through valleys, foothill sections, mountain ranges, and long stretches of desert to Hoover Dam. The line elevation varies from practically sea level to a maximum of 4,862 feet to give an average of 2,400 feet. The isokeraunic level varies from 30 near Hoover Dam to approximately five for the Los Angeles vicinity. The heaviest lightning season for the lines is during the summer and early fall.

Lightning Recording Devices and Their Use

The performance data are obtained through the medium of four types of lightning recording equipment:

Figure 1. Standard single-circuit suspension tower

1. Counterpoise gaps[1] are installed on three legs of the Victorville–Receiving Station E section and on all four tower legs of the remainder of the line. These gaps, installed primarily to prevent corrosion, have proved a reliable means for recording lightning data. They are used to determine the comparative intensity and probable number of lightning strokes on the line. Figure 3 shows the two types of gaps used.

2. Magnetic links (surge-crest ammeters[3]) are installed at select locations along the line totaling 30 miles, where lightning storms are prevalent.

3. Surge recorders with paper indicators are installed on all lightning arresters at the terminals of the lines. While these offer a positive indication of current discharge, they are not accurate for estimating current values. The lightning arresters are equipped also with the magnetic links.

4. Copper lightning rods in series with fusible copper wires, together with magnetic links, are used on the lightning-diverter towers at the Hoover Dam terminal and at the intermediate switching stations. These rod and fuse indicators are installed also on a small number of transmission-line towers.

During the month of May, the transmission lines are practically free of lightning, so this month has been used generally to examine and recondition the installed lightning recording equipment. A lightning year, as designated in this paper, begins about the middle of May and ends about the end of April. Exception to this was the year 1936, which includes some data from the 1934–35 season when the first circuits were under construction.

Since the counterpoise gaps are installed throughout the line, they are relied upon for a good part of the data. Prior to 1943–1944 these gaps were surveyed once a year, but since that time the gaps have been inspected several times a year by the line patrolmen. After the first few years of experience a coding

Paper 50-130, recommended by the AIEE Transmission and Distribution Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 17, 1950; made available for printing April 6, 1950.

T. M. Blakeslee and E. L. Kanouse are with the Department of Water and Power, Los Angeles, Calif.

Figure 2. Map showing geographical location of Boulder 287.5-kv transmission lines

Figure 3. Counterpoise gaps used on the Boulder lines

system was developed to facilitate inspection and report. A sample of the code sheet is shown in Figure 4, and a counterpoise gap survey sheet is shown in Figure 5. For the past three years the average number of flashed gaps per year was 1,250 and at least 15 per cent of these gaps were found to have been flashed over more than once in the same year.

The estimation of the number of lightning strokes from the counterpoise gap data requires some judgment, as a lightning stroke may be direct, involving several towers, or it may be indirect, causing a small burn on only one gap. This is the reason for the designation "probable lightning strokes" used in this paper.

Lightning Performance Data

Figure 6 presents a chart showing the probable number of lightning strokes per line mile per year and the cumulated number of strokes for the 13-year period. The line profile is also shown on this chart, and the correlation between high elevation and high number of strokes is evident from the data, exemplified particularly by conditions in the vicinity of Clark Mountain.

From Boulder switchyard to Victorville the three 287,500-volt circuits have a normal separation of 265 feet. From a lightning standpoint these circuits are treated as one line. From Victorville to Los Angeles, circuit *III* traverses a dif-

Figure 4. Boulder 287.5-kv transmission system lightning survey—counterpoise gap code sheet used by field forces

In coding, Numbers 1 to 12 denote diameter of burn in 20th of an inch.
Numbers standing alone indicate smoked or burned areas without molten metal. Example: 2.
M denotes molten metal. For melted spots use number and *M*. Example: 3*M*.
MS denotes molten metal that has been blown or splashed out.
A denotes a general pitted area. Denote size of such area by numbers and *A*. Example: 3*A*.
G denotes beads or globules of metal.
F indicates solidly fused gap. Use number with *F* to denote diameter of fused column. Example: 2*F*.
M^2 denotes a molten burn. Example: $2M^2$, or $3A^3$, or $2G^4$.
If any type burn occurs inside another type, circle the inner burn. Example: 4*M*(2*G*), meaning 4*M* with 2*G* inside it.

Figure 5. Counterpoise gap service sheet used to collect data

ferent route, as shown in Figure 2; this section is therefore treated as another line, and the data of Figure 6 are presented on this basis. The miles of double-circuit construction for circuits *I* and *II* are indicated on the chart.

The magnetic links, surge recorders, lightning rods, and fuse wires are examined once a year. The low tower footing resistance and the high insulation level on the Boulder lines preclude flashovers on low or moderate values of tower surge currents. In the use of the magnetic links, accuracy on the low values of current is sacrificed in favor of high tower currents, and the two links are placed 6 and 18 inches from the center of gravity of the tower leg instead of the usual three and nine inches. On lightning-rod installations distances for the links of 9 and 27 inches are used.

Since the magnetic-link installations cover only a small portion of the transmission line, the results obtained from them are limited. The curve of Figure 7 presents the data available. The currents plotted are from magnetic-link measurements on all four legs of 107 towers, and are grouped in steps of 5,000 amperes each. Figure 7 presents also the results from 1,987 measurements reported by the Pennsylvania Water and Power Company, and 2,721 measurements reported by Lewis and Foust in the AIEE Transactions.[4,5] The small discrepancy between the Boulder line curves and the other data may result from the large difference in number of records, or it may result from the different methods of using the links.

In the 13 years of operation of the Boulder lines, there have been only two circuit trip-outs attributed to lightning, and one trip-out which probably resulted from lightning but for which the evidence is not definite. The chart of Figure 6 shows that the probable number of strokes to the lines during this period was 2,568, which represents an average of 198 strokes per year. On the basis of three trip-outs resulting from lightning, this is only 0.072 outage per 100 miles of line per year, and 0.032 outage per 100 miles of circuit per year, which is an excellent record and demonstrates the effectiveness of the overhead shielding and counterpoise lightning protective features of these lines.

Summary and Conclusions

1. The counterpoise gap serves as a valuable and inexpensive means of indicating lightning activity on transmission lines equipped with counterpoise.

2. The excellent lightning performance of the Boulder 287.5-kv transmission lines, over the first 13 years of operation, of 0.072 outages per 100 miles of line per year demonstrates the effectiveness of overhead ground wires and continuous counterpoise system.

3. Data from a limited number of magnetic-link installations indicate:

Figure 6. Chart showing probable number of lightning strokes to transmission lines per mile for 13-year period

Figure 7. Distribution of tower lightning currents measured by magnetic links

(a). Oscillatory surge currents predominate over unidirectional currents.

(b). Cloud polarity is predominately negative.

(c). The percentage distribution with respect to magnitude of tower currents compares favorably with published data from other sources.

(d). Tower surge currents are generally not divided equally in the four tower legs.

(e). Some tower surge currents in the order of 100,000 amperes have been recorded on the Boulder line, and these have not caused line flashovers.

Discussion

Abe Tilles (Pacific Gas and Electric Company, San Francisco, Calif.): The excellent record of the line here reported over a long period in quite heavy lightning territory is certainly a heartening evidence that high-voltage circuits can be protected from service interruption due to lightning. Certain questions come to mind.

What are the tower footing resistances on the line with and without the effect of the counterpoise?

Has there been any difficulty in some of the bad soils traversed due to corrosion of the buried counterpoise?

Those of us who may have to keep the "box score" on a well-protected line on which lightning interruption has been reduced practically to the vanishing point meet a problem in exact identification of outages due to lightning. In the two cases listed as sure, and the one doubtful, what evidence pointed to lightning? The authors with their counterpoise gaps, have more evidence than is otherwise available. Did the lightning outages occur during readily identified lightning storms? Was there positive evidence of flashover location additional to the gaps, such as conductor or arcing ring burns, cracked insulators, and so forth?

Was there any indication as to why these three strokes out of the 2,568 hitting the line caused flashovers? How did they compare in current magnitude with others not causing flashover? Were they at insulator strings that might be presumed to be earlier damaged, unusually dirty, or on towers of higher footing resistance than usual?

T. M. Blakeslee and E. L. Kanouse: The authors agree with Dr. Tilles that the Boulder line experience indicates that lightning proof operation of high-voltage lines can be very closely approached. The use of continuous counterpoise on these lines resulted in a maximum measured footing resistance of 7.5 ohms, whereas a limited number of footing measurements made without counterpoise indicated 150 ohms maximum. In a few line locations the buried copper wire has entirely disappeared, leaving a green stain through the soil some two to three inches in diameter. This corrosion, apparently due to corrosive elements in the soil, has not to date resulted in altered line performance. Lightning experience in these localized areas will be watched with a great deal of interest.

It is extremely difficult to prove absolutely the case against lightning in the instances where line flashovers have been laid to that cause. The existence of lightning in the area at the time, the character and size of counterpoise gap burns on adjacent towers, the nature of the burns on the arcing horns, and the lack of any other reasonable cause or evidence, have all had a part in the assignment of cause of flashover in the three cases.

In every case the indication of 60-cycle power follow current given by the counterpoise gap was verified by conditions around an insulator string on that tower. But no indication was had as to the possible terminus of a stroke to the tower or ground wire. Since the flashovers never occurred on towers equipped with magnetic links, no idea of current magnitudes was provided by measurements, and hence no reasons can be advanced as to why the three particular instances appeared in our experience records. Immediate tower footing resistance measurements showed nothing significant.

Automatic Control of Ignitron Rectifier Stations

E. J. CHAM
ASSOCIATE AIEE

W. A. DERR
MEMBER AIEE

THIS paper discusses ignitron rectifier station equipment, operating procedures, and the factors involved in applying automatic control. Reclosing, voltage control, protection, and ground detection are discussed. Considerations involved in applying supervisory control to automatic ignitron rectifier stations are presented. Typical schematic diagrams indicating the components required and the operating procedures established are described for single-unit battery-controlled pumped and sealed ignitron rectifiers with and without anode circuit breakers.

An automatic rectifier station is one in which the rectifier is started and connected to load following an impulse received from a single control device. The operating method established for the rectifier station determines the origin of the starting impulse. The starting impulse may be given by a local operator, by remote operator through supervisory control equipment, by a time switch, or by a load- or voltage-responsive element.

Station Elements

The basic elements of an ignitron rectifier installation consist of a rectifier, a rectifier transformer, and the necessary switchgear equipment. Figure 1 shows these three basic elements. The rectifier transformer is shown at the left, the rectifier in the screened enclosure, and the switchgear at the right. The rectifier and the rectifier transformer remain the same whether the station is automatically or manually controlled. The amount of switchgear equipment is determined by the method of operation, automatic or manual.

Ignitron Rectifiers

The fundamental purpose of an ignitron rectifier is to change electric energy from alternating current to direct current. The ignitron rectifier consists of an assembly of gas-tight evacuated steel containers in each of which there is a graphite main anode, a cathode of mercury, an ignitor, and an auxiliary anode or grid. The individual containers are tied together to form a common cathode for the assembly.

The ignitor is used to initiate the cathode spot for each cycle. Once the cathode spot is started the anode will pick up the current if it is positive with respect to the cathode. The d-c output voltage is determined by the phase connection and secondary voltage of the rectifier transformer, the conduction period, and the small arc drop of the tubes.

The ignitron rectifier has been used for a large percentage of the a-c to d-c conversion installations in the last decade in the mining, railway, industrial, and electrochemical fields. The voltage ranges are for the most part between 250 and 750 volts. However, there has been an increasing number of installations of the 1,500–3,000-volt class.

To provide the necessary vacuum required for operation of an ignitron rectifier the individual containers are either connected to a vacuum system in continuous operation or they are evacuated and permanently sealed. These fundamental methods of maintaining a vacuum have resulted in the common usage of the terms "pumped" and "sealed" ignitrons.

Figure 2 shows a large pumped-type ignitron installation. Figure 3 shows a typical sealed-type ignitron installation. The equipment to maintain a vacuum for a pumped-type ignitron rectifier consists of pumps, equipment for the measurement of pressure, and the necessary protective devices. Economic considerations determine whether pumped or sealed ignitrons are used for a given installation. While the sealed type requires eventual replacement, it does not need vacuum maintaining equipment.

A cooling system is required for all rectifiers to dissipate the heat of the arc and to control the mercury vapor pressure in the ignitron tube. Some form of recirculating water system is used unless a sufficient quantity of clean noncorrosive water at suitable pressure is available for direct cooling.

Rectifier Transformers

Rectifier transformers are essentially power transformers that have been modified to make them suitable for rectifier service. Rectifier transformers are subjected to more severe stresses at frequent intervals than are power transformers because of rectifier arcbacks. Consequently the transformer must be sufficiently braced to handle these repeated stresses. The number and arrangement of windings is determined by the circuits of the rectifier. Voltage, power factor, and regulation depend upon the rectifier-transformer connection and characteristics. The most common connections are the delta 6-phase double-Y and the Y 6-phase double-Y. The delta 6-phase double-Y connection is illustrated in Figure 4.

Most rectifier transformers are provided with taps to compensate for a-c system voltage changes. Taps may also be provided for raising or lowering the voltage applied to the rectifier. The tap-changing equipment may be either the no-load type or underload type and may be automatic or manual.

Paper 50-131, recommended by the AIEE Substations Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 18, 1950; made available for printing April 6, 1950.

E. J. Cham and W. A. Derr are with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

Figure 1. Typical pumped-type ignitron rectifier installation showing rectifier transformer, rectifier, and switchgear

Figure 2. A large pumped-type ignitron rectifier installation

SWITCHGEAR

The switchgear includes the d-c circuit breakers, the a-c circuit breaker, and the protective and control relays. In the application of the switchgear equipment, consideration must be given to the fact that rectifiers are subject to arcbacks. An arcback is failure of the check-valve action, permitting a reversal of current flow between the cathode and the anode. The occurrence of arcbacks in rectifiers is random in nature. Up to the present time it has not been found possible to absolutely eliminate arcbacks. Therefore, the switching means provided for a rectifier must be arranged to prevent damage to any of the components of the installation and minimize service interruptions due to arcbacks.

In early ignitron installations d-c circuit breakers were used only in the cathode circuits. This is still acceptable for many applications. However, during recent years circuit breakers have been used in anode circuits where the rating dictates the desirability of fast fault removal from the transformer or where it is necessary to maintain uninterrupted service during arcbacks. An anode circuit breaker is a multiple-pole device having a circuit-interrupting element equipped with a reverse current device for each anode circuit.

High-speed or semihigh-speed switching is provided for a rectifier depending on the direct voltage, the kilowatt rating of the individual rectifier, and the full-load rating of the station bus. High-speed or semihigh-speed switching can be provided by either cathode or anode circuit breakers.

It is standard practice to provide an a-c circuit breaker capable of interrupting the circuit in 0.13 second or less. The manufacturers have not as yet established definite circuit-interruption times for high-speed or semihigh-speed d-c circuit breakers.

The control relays are applied to fit the operating methods adopted for the station. They govern the starting and stopping sequences employed. Protective devices provide for shutdown of the ignitron rectifier for conditions which could result in damage to equipment if maintained. The number and type of protective devices used is determined by the size and operation of the installation.

Single-Line Diagram

Figure 4 indicates the main power connections for a typical single-unit single-way 6-element ignitron rectifier, with a delta 6-phase double-Y transformer. This diagram applies to either the pumped- or sealed-type ignitron rectifier. Instrumentation for local quantities is simple. Alternating and direct current and voltage are quantities of interest. Either a-c or d-c kilowatt-hours are usually metered. The telemetering transmitters which would be used for a station operated by supervisory control are not shown on the diagram.

An interphase transformer is not effective when there is no load on the rectifier and a higher direct voltage results. With reference to Figure 4, this higher voltage occurs since the rectifier transformer functions as a delta 6-phase star rather than as a delta 6-phase double-Y, with no load on the rectifier. Therefore, when an interphase transformer is used, a light-load voltage suppressor is necessary to limit the voltage rise when there is no connected load. The value of this resistor is such that it applies a lead of less than 1/2 per cent of the kilowatt rating of the ignitron rectifier. The light-load application relay, device 37 (see Appendix), is sometimes omitted on units of small kilowatt rating and the light-load voltage suppressor is then permanently connected to the output terminals.

Figure 3. Typical sealed-type ignitron rectifier installation

Figure 4. Single-line diagram of a single-unit ignitron rectifier station

Excitation and Cooling System Circuits

Figure 5 shows a typical saturating reactor-capacitor network excitation circuit for a pumped or sealed ignitron, as well as the recirculating water pump contactor. All the devices on this diagram are connected to the 3-phase rectifier auxiliary transformer, the primary of which is connected to the line side of the a-c circuit breaker *52*. The excitation system should be connected to the same source as the main transformer since the excitation must be synchronized with the anode voltages.

The feed transformers, *P1*, *P2*, *P3*, supply the energy in the correct phase relationship to the network. The firing capacitor *CF* is charged through phase shifting reactor *XPS*. The capacitor voltage is continuously applied to the saturating reactor *XS* until the current reaches a value at which the reactor *XS* saturates. At this point the capacitor is discharged through reactor *XS* and a large peak current passes through the ignitor. This peak current or ignitor impulse creates the cathode spot within the ignitron. By the use of dry-type rectifier units it is possible for one circuit to supply two ignitrons which are diametrically opposite in phase position in the rectifier circuit.

The variable-voltage transformer is used to apply voltage to the full-wave dry-type rectifier. This makes it possible to vary the saturating current in the d-c coil of the phase-shifting reactor *XPS*, which results in a change of the phase position of the ignitor impulse.

With transfer switch *43* in the degas position, contacts of device *31*, connected between the saturating reactor *XS* and the ignitor dry-type rectifiers, short-circuit the ignitors when the coil of device *31* is energized by the closing of contact *63VX* on high ignitron tank pressure. Degassing is the process of removing occluded gases from internal parts of the ignitron by passing current through it. The liberated gases are removed by the vacuum pumps. Degassing is required only on initial installation or when a tank has been opened for inspection or repair. Since, during degassing, tank pressure is erratic, it is not desirable to shut down the rectifier completely each time tank pressure is high; therefore, the ignitors are merely short-circuited by device *31*. This stops rectification. After the tank pressure returns to normal, the coil of device *31* is de-energized by the opening of contact *63VX*. Contacts of device *31* open and the short circuit across the ignitors is removed. The coil circuit of device *31* can be modified so that certain operating conditions short-circuit or release the ignitors to start or stop rectification without circuit breaker operations.

To insure that the anodes pick up current when the ignitor pulse occurs, a voltage is impressed on the auxiliary anode or grid, leading the no-delay ignition impulses by a fixed number of degrees. The grid transformers in Figure 5 have a resistor in series with each grid to limit the current. A lamp connected across the resistor will give misfire indication. During each cycle that the main anode fails to conduct current because of a misfire of the ignitor, no current will flow in the grid circuit. The lamp will thus not be energized on a misfire. When a rectifier station is operated by supervisory control, the lamps can be replaced by relays to provide an alarm following a sustained misfire.

Figure 6(A) shows the voltage relations of a delta 6-phase double-Y rectifier circuit. As previously mentioned, the

Figure 5. Typical ignitron rectifier excitation schematic diagram

Figure 6. Diagram showing instantaneous rectifier anode voltage relationships (a) without phase delay and (b) with 30-degree phase delay

Figure 7 (above). Typical vacuum system control for pumped-type rectifiers

Figure 8 (right). Partial control schematic diagram applying for ignitron rectifiers with and without anode circuit breakers

ignitor is used to initiate the cathode spot for each cycle. Once the cathode spot is started, the anode will pick up the current if it is positive with respect to the cathode. With no firing delay, a cathode spot is formed in the ignitron at times *A*, *B*, *C*, *D*, *E*, *F*, and *G*, and the current will transfer consecutively from ignitrons *5* to *1*, *1* to *3*, *3* to *5*, *5* to *1*, and so forth, for group *1-3-5*, and *6* to *2*, *2* to *4*, *4* to *6*, *6* to *2*, and so forth, for group *2-4-6*. The resultant direct voltage is the average of the direct voltage produced by group *1-3-5* alone and the direct voltage produced by group *2-4-6* alone.

Figure 9. Circuit breaker control schematic without anode circuit breakers

Figure 6(B) shows the voltage relations with a 30-degree delay in the ignitor impulse. By comparing Figures 6(A) and 6(B) it can be readily seen that delaying the ignition impulse of each ignitron reduces the voltage output. Control of the relative phase position between the ignitor pulses and the anode voltage provides a means of voltage control.

The operating voltage for the saturating reactor-capacitor network excitation circuit should be above 95 per cent of normal rated voltage for starting. Also, the phase rotation of the 3-phase voltage applied to the excitation circuit must always be the same. Device *47* detects all of these conditions and functions to prevent starting unless all are correct.

For operation after starting, the voltage for the excitation circuit can be considerably less. Therefore, the low-voltage setting of device *47* is determined by the operating range of the automatic control devices connected to the alternating voltage.

Device *8E* is the excitation contactor which is energized by the master relay *4*. Device *8E* is provided with thermal trip elements to de-energize the excitation circuit whenever the input-current magnitude indicates a fault in the excitation circuit. An open-circuited ignitor results in high unbalanced currents in the excitation circuit which, if allowed to continue, would damage the equipment.

The simplest method of operation when a recirculating water pump is required is to have the pump run continuously. This method is shown in Figure 5 where device *88WX* is the motor contactor. The pump motor device *88W* is shown in Figure 7. The pump motor can also be individually controlled or its starting and stopping can be incorporated as part of the automatic sequence. It can be started by the master relay *4*. For such automatic operation, when the rectifier is shut down, it is desirable to provide a timing circuit which allows the pump to continue running for a short time to completely cool the rectifier.

When a recirculating water cooling system is used, a water-to-water or water-to-air heat exchanger is required. In the case of the water-to-air heat exchanger the blower-fan motor is automatically controlled by a thermal element in the water system. When conditions are such that the cooling water can reach extremely low temperatures when the rectifier is not in operation, a thermally controlled water heater is desirable.

Vacuum System

Figure 7 shows all of the electrical devices involved in the vacuum system for pumped-type rectifiers as well as the recirculating water pump motor previously mentioned. Devices *88VX*, *88V*, *26V*, the mercury-vapor vacuum pump, and hot wire gauge are mounted on the rectifier frame which is at cathode potential. The remaining devices are located in the rectifier auxiliary cubicle. The auxiliary cubicles are shown to the left of the rectifiers in Figure 2. The insulating transformer is used to keep cathode potential from the devices not mounted on the rectifier.

The mercury-vapor pump consists of a cylinder containing a pool of mercury which is heated by an electric heater. The mercury vapor is directed through nozzles carrying along the gases from the ignitron tanks. The mercury vapor condenses on the cool walls of the cylinder and the gases are removed by a motor-driven rotary oil-sealed vacuum pump *88V*. The rotary oil-sealed vacuum pump consists of a cylinder with an eccentrically mounted rotor and sliding vanes which compress the gases from the mercury-vapor pump and discharge them into the atmosphere.

The hot-wire vacuum gauge is a Wheatstone bridge with one leg consisting of a wire having a high temperature coefficient of resistivity enclosed in a tube connected to the ignitron rectifier vacuum system. The higher the pressure of the gas, the higher is its thermal conductivity and the lower is the temperature and resistance of the wire. The resistance is therefore a direct measure of gas pressure. The vacuum meter is calibrated in microns. Device *63V* detects pressure in excess of the safe operating range and contact *63VH* short-circuits device *63VX*

Figure 10. Circuit breaker control schematic with anode circuit breakers

Figure 11. Diagram of typical automatic recloser

causing it to release. When the pressure returns to normal, contact *63VL* energizes device *63VX*.

Automatic Sequence for Ignitron Rectifiers without Anode Circuit Breakers

The starting and stopping sequences for a single ignitron assembly of either the pumped or sealed type without anode breakers are described in the following paragraphs. Figures 4, 5, 8, 9, and 11 apply for the description to be given.

Starting

With reference to Figure 8 the *1-start* contact may be a contact of a local pushbutton, a contact operated by supervisory control, or a contact actuated by time, load, or voltage. Closing the *1-start* contact energizes auxiliary starting relay *1X* which seals itself in. With relay *1X* energized the rectifier will continue to operate or be ready to again start unless locked out by a protective relay. Relay *1X* remains energized until short-circuited by the *1-stop* contact. If lockout relay *86* is reset and relays *5* and *94* are de-energized, master relay *4* will be energized by the make contact of relay *1X*.

Referring to Figure 5, a make contact of master relay *4* energizes contactor *8E* which applies voltage to the excitation circuit. Referring to Figure 9, another contact of master relay *4* energizes the closing relay of a-c circuit breaker *52* through a *b* auxiliary switch of cathode circuit breaker *72*. When voltage appears on the rectifier terminals to energize d-c relay device *80*, the cathode circuit breaker *72* closing relay is energized through a make contact of master relay *4*, an *a* auxiliary switch of circuit breaker *52*, and a make contact of device *80*. This sequence places the ignitron rectifier in complete operation and connects it to the load or system.

The variable-voltage transformer in the phase-shift circuit can be varied to adjust load or voltage. A voltage or current regulator can be applied in the phase-shift circuit to control automatically the output voltage or current. This method of control is only used for changes that are of a relatively small magnitude since delaying the rectifier ignition to reduce the load or voltage decreases the power factor and increases amplitude of the harmonics of the system. For large installations where power factor is important, the rectifier transformers are equipped with underload tap changers to vary the a-c input voltage to the rectifier and thereby vary the d-c output. Whether the tap changer is automatic or manual is determined by the method of operation for the station. The use of tap-changer equipment is not considered in the diagrams presented.

Stopping

With reference to Figure 8, the *1-stop* contact may be a contact of a local pushbutton, a contact operated by supervisory control, or a contact actuated by time, load, or voltage. When the *1-stop* contact is closed momentarily, it short-circuits relay *1X* and causes it to release. When relay *1X* releases, it de-energizes relay *4*.

Referring to Figure 9, a break contact of relay *4* completes the circuit to the trip coil of a-c circuit breaker *52*. A *b* auxiliary switch of a-c circuit breaker *52* completes the circuit to the trip coil of cathode circuit breaker *72*. With reference to Figure 5, the release of relay *4* de-energizes device *8E* which removes voltage from the excitation circuit. This completes the normal shut-down of the rectifier.

Operation of Arcbacks

If the rectifier is the only source of power for a nonregenerative load, an arcback will cause the closing of the instantaneous contacts of the a-c overcurrent relay *51*. These contacts are designated on the diagrams as *51I*. With reference to Figure 9, device *94* is energized when contact *51I* closes. Relay *94* seals in. Several times rated voltage is applied to relay *94* to insure high-speed operation. Contacts of device *94* trip the a-c circuit breaker *52* and the cathode circuit breaker *72*. Another contact of device *94* short-circuits master relay *4* and causes its release. The release of master relay *4* de-energizes device *8E* which in turn de-energizes the excitation circuit. This completes shut down of the rectifier.

With reference to Figure 11, another make contact of relay *94* energizes the motor of the automatic recloser. After a predetermined time interval the operation of the recloser motor results in the closing of recloser contact *79Y*. The detailed operation of the recloser will be described later.

Referring to Figure 9, recloser contact *79Y* short-circuits relay *94* and causes its release. The release of relay *94* allows master relay *4* to again be energized and the rectifier is started the same as on initial start. The automatic recloser device *79* can be arranged to provide one, two, or three reclosures. If the shutdown of the rectifier resulted from a random arcback, experience has indicated that service will be restored with a single reclosure. If the shutdown of the rectifier resulted from a permanent fault, repeated reclosures may result in possible damage to equipment. Therefore, it is customary to provide for only a single automatic reclosure.

With reference to Figure 8, it will be noted that a circuit to the lockout relay *86* is completed through contacts of relay *94* and auxiliary reclosing relay *79Z*. If reclosing is unsuccessful, both of these contacts will be closed to energize the lockout relay. Lockout relay *86* opens the circuit to master relay *4* and prevents restarting of the rectifier until the lockout relay *86* is manually reset.

Figure 12. Typical annunciator schematic diagram

If the rectifier is not the only source of power, an arcback results in the operation of reverse current device *32C*, shown in Figure 4. Reverse current trip device *32C* is provided as a part of the cathode circuit breaker mechanism and its actuation trips the cathode circuit breaker in a minimum of time. All of the other operations including the tripping of the a-c circuit breaker and operation of the recloser are the same as just described for the condition with nonregenerative load.

Automatic Sequence for Ignitron Rectifiers with Anode Circuit Breakers

The starting and stopping sequences for a single ignitron assembly of either the pumped or sealed type with anode breakers are described in the following paragraphs. Figures 4, 5, 8, 10, and 11 apply for the description to be given. Figure 10 is based on an anode circuit breaker with six individual poles with a single motor-operated closing mechanism. Each pole has an individual latch-holding coil which must be energized to keep the pole in the closed position after it has been closed by the motor-operated mechanism. Operation of the motor-closing mechanism of the anode circuit breaker will close any number of poles that are open. The latch-holding coils are devices *7HC1* to *7HC6* inclusive. These latch-holding coils are usually energized by a contact of the starting relay *1X* as shown in Figure 10. In some cases these latch-holding coils are left continuously energized. Each pole of the anode circuit breaker is also equipped with a reverse current trip device *32A* as shown in Figure 4. On reverse current, device *32A* overcomes the flux of the latch-holding coil to trip the pole.

Starting

The starting sequence is exactly the same as previously detailed for ignitron rectifiers without anode circuit breakers except for the additional operation of closing the anode circuit breaker. The closing mechanism of the anode circuit breaker is energized as soon as the a-c circuit breaker is closed through an *a* auxiliary switch of the a-c circuit breaker *52*, and a break contact of device *94* as shown in Figure 10. The closing of the cathode circuit breaker is determined by device *80* just as in the case without anode circuit breakers.

Stopping

The stopping sequence is the same as previously described for ignitron rectifiers without anode circuit breakers except for the additional operation of opening the anode circuit breaker by de-energizing the latch-holding coils *7HC1* to *7HC6*, inclusive.

Operation on Arcbacks

Operation on arcback is the same whether the rectifier is the only source of power or if it is paralleled with other sources of power. In either case the current reverses in one or more of the individual ignitron tubes. This results in operation of the reverse current devices *32A* which trip the anode circuit breaker poles connected to the faulted ignitrons. All of the unfaulted ignitrons remain in service and continue to supply load.

With reference to Figure 10, it will be noted that device *7A* is energized only when all of the anode circuit breaker poles are closed. When an arcback results in one of the breaker poles opening, device *7A* is de-energized. A break contact of relay *7A* energizes relay *94* through an *a* auxiliary switch of cathode-breaker *72*. Relay *94* seals in. The break contact of relay *94* opens in the closing circuit of the anode circuit breaker to release the antipump relay not shown.

With reference to Figure 11, a make contact of relay *94* energizes the motor of the recloser *79*. After a predetermined time interval the operation of the recloser motor results in the closing of the recloser contact *79Y*. Referring to Figure 10, recloser contact *79Y* short-circuits relay *94* and causes its release. The release of relay *94* completes the anode circuit breaker closing circuit to close the opened pole. This returns the unit to normal operation. If the arcback repeats within a definite time interval, the anode pole connected to the faulted ignitron will again open as just described.

The automatic recloser *79* can be arranged to provide one, two, or three reclosures. It is customary to provide only one reclosure to prevent possible damage to equipment. Assume the automatic recloser device *79* is arranged for a single automatic reclosure. Then relay *79Z* in Figure 8 will still be closed if the anode circuit breaker pole trips within a definite time interval after the first reclosure. With relay *94* being again energized by the break contact of relay *7A*, a circuit is completed to lockout relay *86* in Figure 8. Lockout relay *86* opens the circuit to master relay *4* which stops the rectifier as previously described. Lockout relay *86* must be manually reset before the rectifier can be restarted. It should be noted that neither the a-c circuit breaker nor the cathode circuit breaker operates on arcback. The a-c circuit breaker and the d-c circuit breaker only provide back-up protection on arcback. The cathode circuit breaker does not have a reverse current trip device.

Automatic Recloser

The automatic recloser *79* consists of a synchronous motor-driven set of cams and relays *79X* and *79Y*. The cam contacts are designated as *79-1* to *79-4*. The circuits are arranged so that once the synchronous motor *79M* is energized it will continue to run until the start or lockout position is reached. When the recloser is in the start position it is ready to effect a reclosure.

In the start position, cam contact *79-1*

is closed and all other cam contacts are open. When relay *94* operates on arcback, recloser motor *79M* is energized through cam contact *79-1*. Cam contact *79-2* closes after the mechanism starts to move and remains closed until the start position is reached. Cam contact *79-1* is closed at all times except between the lockout and start positions. Cam contact *79-3* is adjustable and can be set to obtain the desired time of the reclosure. Cam contact *79-3* can be closed one, two, or three times for a complete cycle of the recloser. Cam contact *79-4* closes in the lockout position and opens when the start position is reached.

After an arcback, the closing of relays *79X* and *79Y* is governed by the closing of cam contact *79-3*. Relay *79X* is energized first and it in turn energizes relay *79Y*. When the circuit breaker recloses, the coils of relays *79X* and *79Y* are de-energized. However, a latching arrangement prevents relay *79Y* from completely releasing until cam contact *79-3* opens. This latching arrangement allows reclosing contact *79Y* to open but keeps contact *79Y1* closed and contact *79Y2* open. Thus, relay *79Y* is only energized for as many times as cam contact *79-3* closes during a complete cycle and prevents pumping of the circuit breaker.

If the circuit breaker remains closed after a reclosure, the recloser is run to the start position through cam contact *79-2*. If the circuit breaker trips after being reclosed before the recloser reaches the start position, it is run to the lockout position through the cam contact *79-1* and a make contact of relay *94*. After the lockout position is reached, the reset push button must be operated to run the recloser to the start position.

Protection

In addition to the protective devices required to detect arcback and result in the interruption and subsequent automatic restoration of service, an automatic rectifier installation requires other protective devices. These protective devices are usually arranged to either lock the unit out of service until manual reset of a lockout relay or to stop the unit with automatic restarting allowed when the trouble no longer exists.

The following listings indicate for a typical installation the trouble conditions which initiate lockout and those which merely stop the rectifier with automatic starting allowed. Examples of shutdown and lockout are:

1. A-c overcurrent for a definite time interval (*51T*).
2. An open ignitor (*8E*).
3. High rectifier temperature (*26H*).
4. Unsuccessful automatic reclosing (*79*).
5. Low pressure of cooling water (*63WC*).
6. High temperature of mercury-vapor vacuum pump (pumped type only, *26V*).

Examples of shutdown with automatic restarting are:

1. Single phase, reverse phase, or low auxiliary voltage (*47*).
2. Thermal overload (*49*).
3. Transformer overtemperature (*26T*).
4. Loss of vacuum (pumped type only, *63V*).

Lockout relay *86* and stopping relay *5* are shown in Figure 8. When lockout relay *86* is energized, it opens the coil circuit of master relay *4* and stops the rectifier. Lockout relay *86* must be manually reset to restore the circuit for master relay *4*. A make contact of stopping relay *5* short-circuits the coil of master relay *4* and causes it to release. When stopping relay *5* is de-energized, master relay *4* will be again energized if the contact of lockout relay *86* is closed and the starting relay *1X* is energized.

Lockout relay *86* is directly energized by the protective circuits for a-c overcurrent, unsuccessful automatic reclosing, and for an open ignitor. When oil-filled rectifier transformers are used, lockout relay *86* is also directly energized by a low oil level contact. The protection for low transformer oil level is not shown in Figure 8. It is to be noted that the protective circuits for high rectifier temperature (*26H*), high temperature of the mercury-vapor pump (*26VX*), and low cooling water pressure (*63WC*) are connected to the lockout relay *86* through a make contact of relay *43TX* and to stopping relay *5* through a break contact of relay *43TX*. Relay *43TX* is an auxiliary to timing relay *43T*. This arrangement is provided so that operation of devices *26H*, *26V*, and *63WC* results in shutdown and lockout if the rectifier has been in service for a definite period of time (usually ten minutes), but only prevents starting for this time interval if the rectifier has been shut down because of loss of or low alternating voltage. This is done to avoid a lockout when during shutdown the latent heat of the rectifier units may operate devices *26H* and *26V*. Likewise, device *63WC* may operate because of low voltage on the pump motor.

Stopping relay *5* is energized by the protective circuits for thermal overload, transformer overtemperature, loss of vacuum, and improper a-c auxiliary voltage.

Device *47*, which detects single-phase, reverse-phase, and low auxiliary voltage, has a *47H* contact which closes only if all voltage conditions are correct and the magnitude of the voltage is at least 95 per cent of normal. If the voltage conditions are not correct and the voltage magnitude is less than 85 per cent of normal, contact *47L* will close. Contacts *47H* and *47L* are connected to auxiliary relay *47X* so that 95 per cent of normal voltage must be available for starting, and, if the voltage drops to less than 85 per cent after starting, the rectifier is shut down.

Device *49*, which detects thermal overload of the rectifier installation, has a contact *49H* which closes on high temperature and energizes device *49X*. De-

Figure 13. Ground detection schematic which applies when structure is insulated from ground

vice *49X* energizes relay *5* which shuts down the rectifier in the usual manner. When the rectifier unit cools sufficiently, contact *49L* of device *49* short-circuits device *49X* which releases relay *5* to allow restarting.

A contact of auxiliary vacuum relay *63VX* will energize stopping relay *5* for poor vacuum if the degassing switch is in the normal operating position. The degassing switch contact is used in this circuit to avoid shutdown during degassing when vacuum conditions are erratic.

Device *37*, which detects loads of less than one-half per cent of normal rating, has a *37L* contact which closes under such a condition to energize device *37X*. Device *37X* applies the light-load voltage suppressor to the rectifier. When the output of the rectifier exceeds one-half per cent of normal rating, contact *37H* closes to short-circuit device *37X* and causes it to release and disconnect the light-load voltage suppressor.

All of the conditions which result in shutdown of a rectifier are usually annunciated. A typical annunicator arrangement is shown in Figure 12. The annunciator *30* consists of drops and a latching alarm relay. Closing of any of the protective circuits energizes an individual drop in series with the operating coil *30-0* of the latching relay. Operation of the annunciator drop opens its circuit. Operation of relay *30-0* completes a circuit to an alarm bell. Closing the bell cutoff contact energizes the reset coil *30-R* of latching relay and silences alarm.

A different annunciator arrangement is sometimes used to reduce the number of protective relay contacts required. In this arrangement the annunciator drops are connected in the same protective relay circuits which energize relays *5* and *86*.

Grounding

When neither the positive nor negative output of the rectifier is grounded, the rectifier is insulated from ground. For such ungrounded service it is usually desirable to solidly ground the rectifier excitation cubicle, as well as all of the switchgear panels and structures.

If the negative of the rectifier is grounded, it is necessary to insulate the rectifier unit from ground. For such grounded service a d rectifier voltages up to 300 volts it is customary to solidly ground the rectifier excitation cubicle, as well as all of the switchgear panels and structures. However, for rectifier voltages above 300 volts it is customary to insulate the rectifier excitation cubicle, as well as all of the switchgear panels and structures, with a single connection to ground being provided through a high-resistance ground detecting relay circuit.

Figure 14. Front view of supervisory control dispatching office cabinet for the control of a large ignitron rectifier station

Figure 13 shows devices to detect accidental grounding or contact of the rectifier excitation cubicle, switchgear panels, or structure with the ungrounded side of the rectifier output. Device *64X* detects an accidental ground. The moving contact of relay *64X* maintains a position between two stationary contacts when there is no ground on the structure and when there is no break in the circuit from the relay to the structure or to ground. If the structure becomes accidently grounded the moving contact of relay *64X* will move to one of the stationary contacts. If the circuit from the relay to the structure or ground is opened, the moving contact of relay *64X* will move to the other stationary contact. Thus, relay *64X* detects an accidental ground on the structure and continuously checks that the ground detecting circuit is intact. Device *64* detects accidental contact of the ungrounded side of the d-c bus with the structure. Upon accidental contact rectifier potential is applied to relay *64* causing it to be energized. When applied, operation of relay *64* results in rectifier lockout. Relay *64X* is usually only annunciated.

Parallel Operation

The arc drop of an ignitron rectifier remains essentially fixed from light load to rated load. The major voltage drop is due to the resistance and reactance of the transformer. Both the reactance and resistance drops are directly proportional to the load currents. Therefore the regulation curve of an ignitron rectifier is virtually a straight line. This simplifies paralleling of several rectifiers as well as paralleling with other conversion equipment.

Parallel operation may be accomplished by matching the voltage regulation characteristics of the rectifier with the paralleled apparatus, or by automatically adjusting the voltage output of the rectifier to that of the paralleled apparatus by the means of a voltage regulator.

Supervisory Control

Economic considerations often result in the use of supervisory control equipment to provide the necessary controls and indications for an automatic rectifier station.

Supervisory control equipment can be operated over a single pair of telephone wires, a power-line carrier channel, or a microwave radio channel. A single channel is all that is required regardless of the number of controls, lamp indications, and selective telemetered indications required. Following is a list of typical supervisory control functions for an ignitron rectifier station:

1. Control and supervision of master starting relays of the rectifiers.
2. Control of each rectifier output with simultaneous telemetering of rectifier amperes or kilowatt output.
3. Control of each rectifier voltage with simultaneous telemetering of rectifier voltage.
4. Control and supervision of d-c feeder circuit breakers.
5. Control and supervision of all a-c circuit breakers other than the rectifier circuit breakers.
6. Supervision of cathode circuit breakers.
7. Supervision of anode circuit breakers.
8. Supervision of rectifier lockout.
9. Supervision of annunciator (if any quantities are annunciated that do not shut down rectifiers).
10. Supervision of ignitron misfire.
11. Supervision of local-remote transfer switch.
12. Communication.

The supervisory control at the rectifier station is usually incorporated as part of the local switchboard.

Figure 14 shows the front of a supervisory control dispatching office unit for the control of a rectifier station. It will

be noted that the plates which mount the supervisory control keys and lamps are located in a mimic bus arrangement.

Conclusions

Ignitron rectifiers are well suited for automatic operation since the starting and stopping sequences are quite simple. Hence, automatic control is employed in a large percentage of ignitron rectifier installations.

Devices are available to provide for any reasonable operating requirements. Supervisory control and telemetering operating over line wires, power-line carrier, or microwave radio channels makes it possible to obtain many desirable operating features for completely unattended installations.

Developments in equipment and methods of operation in recent years have made it possible to improve the service factor of rectifier installations and have made operation and maintenance simpler.

Appendix. Devices Designated in Illustrations

1—Start-stop elements
1X—Auxiliary starting and stopping relay
4—Master relay
5—Automatic stopping relay
7—Anode circuit breaker
7A—Auxiliary relay operated when all anode circuit breaker poles are closed
7HC—Anode circuit breaker latch-holding coils
8E—Excitation contactor
26H—Rectifier thermal device
26T—Rectifier transformer thermal device
26V—Mercury vacuum thermal device
26VX—Auxiliary relay to device *26V*
30—Annunciator relay
30-1 and so on—Individual drops
30-0—Operate coil to sound alarm
30-R—Reset coil to silence alarm
31—Ignitor shorting relay
32—Reverse current device
32A—Anode circuit breaker
32C—Cathode circuit breaker
32P—Polarizing coil
37—Light-load application relay
37H—Closes on high current
37L—Closes on low current
37P—Polarizing coil
37X—Auxiliary contactor to device *37*
43—Transfer switch
43D—Closed in degas position
43N—Closed in normal operating position
43T—Timed lockout transfer relay
43TX—Auxiliary relay to device *43T*
47—Single, reverse-phase and low-voltage relay
47H—Closes for normal voltage conditions
47L—Closes for reverse phase, single phase and low voltage
47X—Auxiliary to device *47*
49—Thermal overload relay
49H—Closes for high temperature
49L—Closes for normal temperature
49X—Auxiliary to device *49*
51—A-c overcurrent relay
51I—Instantaneous element
51T—Timed element
52—Rectifier a-c circuit breaker
63V—Vacuum relay
63VH—Closes high pressure
63VL—Closes on normal pressure
63VX—Auxiliary to device *63V*
63WC—Circulating water pressure
64—High-resistance structure-grounding relay
64X—Structure ground-detection relay
64XP—Polarizing coil
72—Cathode circuit breaker
79—Reclosing relay
79-1 to *79-4*—Motor-operated cams
79M—Synchronous motor
79X—Recloser relay element
79Y—Recloser relay element
79Z—Auxiliary reclosing relay
80—Rectifier voltage indication relay
86—Lockout relay
88V—Vacuum pump motor
88VX—Vacuum pump motor contactor
88W—Recirculating water pump motor
88WX—Recirculating water pump motor contactor
94—Arcback relay
CF—Firing capacitor
L1-L6—Misfire indication lamps
XPS—Phase-shifting reactor
XS—Saturating reactor

Discussion

Ralph Siegel (General Electric Company, Schenectady, N. Y.): This paper describes the ignitron rectifier station equipment and the arrangements for its automatic operation, switching, control, and relaying. Its presentation is based on the methods practiced by one manufacturer. Other manufacturers have different methods to accomplish the same results and this paper should not be interpreted as the practices employed by them. In addition, the mode of operation is subject to change, depending upon specific user requirements. There are several portions of this paper that should be amplified.

In the discussion of the ignitron rectifier, mention is made that the direct voltage output is determined by the phase connection and secondary voltage of the power transformer, the conduction period, and the arc-drop of the tubes. In addition, the system impedance is often extremely important. Poor regulation or unexpected voltages will result when it is not taken into consideration. This factor is especially important in the chemical and building service industry and where low direct voltages, such as the 250-volt class, are required.

The authors state that economic considerations determine whether pumped or sealed ignitrons are used for a given installation. In the final analysis this is true, but other factors do enter into the application or selection of a rectifier. Of prime consideration is the current-carrying ability of the tubes or tanks at a particular direct voltage. Larger blocks of power can be concentrated in the pumped tanks with a resultant decrease in material, ease of handling, and concentration of control than if functionally similar sealed tubes are used.

The subject of the operation of the rectifier with arc back requires some amplification. Arc back as described by the authors is random in nature. However, it is an infrequent occurrence that manifests itself near the end of the tube life or at the time when the tanks need reconditioning. More on this subject can be read in the paper by J. W. Seaman and L. W. Morton presented in 1942.[1]

When a power circuit breaker and separate protective relays are required in the primary of a rectifier transformer rated above 600 volts alternating current, these relays should be of the induction disk overcurrent type. Adjustable time delay relays are more satisfactory than the instantaneous type because they can be set lower than the instantaneous relays in order to override the transformer magnetizing inrush. They will also allow more selectivity with the d-c circuit breaker. Better performance can, therefore, be obtained by using time delay overcurrent relays.

When anode circuit breakers are not used these low set relays should be of short time delay type in order to clear the a-c system in the shortest possible time when arc back occurs. Instantaneous attachments, high set, can also be used to clear a-c system faults or internal transformer faults.

When high-speed anode circuit breakers with built-in reverse current tripping devices are used, the induction disk time delay overcurrent relays can be of the standard speed to give the same protection as other system relays. In this case, arc back protection is obtained by a reversal of current through the high-speed anode circuit breaker. Thus the overcurrent relays are not required to function on arc back.

On a-c systems of 600 volts or less, dual-magnetic overcurrent trips on the circuit breaker are generally used in the transformer primary. The instantaneous trips in this case are set high enough so that the circuit breaker will not trip on magnetizing inrush, but will trip in case of rectifier arc back. The current setting of the time delay element should be adjusted to carry the short-time overcurrent rating of the rectifier. When an overcurrent cathode circuit breaker is present, the setting can be higher so that selectivity can be obtained with the cathode circuit breaker.

Under the subject of protection, an item for persistent misfire has been omitted. Persistent misfire can be caused by any of the following:

1. Gassy tube or tank.
2. Short-circuited or wetted ignitor.
3. An open circuit of the ignition system (covered by the paper).

Such a condition should cause the rectifier to shut down and lock out if not cleared within a definite time.

In general the conditions that cause shut down and lock out are:

1. Arc back.
2. Misfire for longer than a predetermined time.
3. Incompleted sequence of operation.
4. Severe a-c overcurrent.
5. D-c short circuit not cleared by sectionalizing equipment.

While conditions causing a temporary outage, holding the rectifier in readiness to automatically come on the line as soon as the condition has been rectified are:

1. Improper water pressure or loss of water.
2. Temperature of cooling water too high or too low.
3. Insufficient vacuum (pumped rectifiers).
4. Transformer overtemperature.
5. Low, single phase, or reverse phase sequence for a-c supply voltage.

The authors have stated that high rectifier temperature, low cooling water pressure, and high temperature of the mercury vapor pump cause shut down and lock out. This is not necessary as the facilities are available to allow these conditions to be automatically corrected. Of course, if the rectifier is not temporarily shut down while the conditions are automatically taking care of themselves, then the rectifier will arc back and cause shut down and lock out.

The subject of parallel operation should be amplified. It is necessary to match the voltage characteristics of the rectifier with the paralleled apparatus as explained by the authors.

However, this is not the only item to be taken into consideration when a rectifier is paralleled with other equipment. Insofar as the a-c circuit is concerned the addition of a rectifier does not change the interrupting requirements of the a-c circuit breaker. On the d-c equipment this is not true and the additional contributions must be reckoned with. The interrupting requirements are usually increased when a rectifier is paralleled on a bus with other d-c generating or conversion apparatus.

1. A NEW MULTIPLE HIGH-SPEED AIR CIRCUIT BREAKER FOR MERCURY-ARC RECTIFIER ANODE CIRCUITS AND ITS RELATION TO THE ARC-BACK PROBLEM, J. W. SEAMAN, L. W. MORTON. *Electrical Engineering* (*AIEE Transactions*), volume 61, November 1942, pages 788–96.

E. J. Cham and **W. A. Derr:** A large part of Mr. Siegel's discussion is either confirmation or amplification of some of the statements made in our paper.

Most of Mr. Siegel's discussion requires no comments. We will only comment on the items which Mr. Siegel has questioned or on any of his amplifications with which we do not agree.

With reference to the first paragraph of Mr. Siegel's discussion, it should be noted that throughout the paper we referred to the diagrams as typical. Obviously, special applications require special consideration and were not intended to be within the scope of this paper.

Mr. Siegel's statement, "In addition the system impedance is often extremely important" is an overstatement. We have found it only occasionally important in paralleling of rectifiers with other conversion equipment. We have found it important on one installation within the last eight years.

Mr. Siegel states that better selectivity with the d-c circuit breaker can be obtained on systems of 600 volts or more, by the use of adjustable time delay relays instead of instantaneous relays. It should be noted that this selectivity is obtained at the expense of delayed tripping during arc back which is the most damaging fault to which rectifiers are subjected. If during arc back the high current is allowed to continue it may damage the tube and/or the rectifier transformer. There are two requisites for best protection under arc back conditions: high speed and selectivity. This is true regardless of voltage. Using an instantaneous trip gives maximum high-speed operation under arc back conditions. There are some cases in which the setting of the instantaneous trip element is rather critical to obtain selectivity. When anode circuit breakers are used the instantaneous trip is omitted, (Figure 10 of our paper) as rectifiers equipped with anode circuit breakers possess a very high degree of selectivity.

The following sentence is quoted from a recent report[1] AIEE entitled Protection of Electronic Power Converters by the Committee on Electronic Power Converters: "Instantaneous element (50) to trip quickly in case of tube arc back or transformer fault. This relay should be set slightly in excess of the transformer current inrush and the short time rating of the rectifier".

It is to be noted that our paper is in accord with this AIEE Committee recommendation.

Figure 5 of our paper shows misfire indicating lamps. Our paper also states that these lamps may be replaced by relays to provide an alarm following a sustained misfire. This relay would give an alarm on sustained misfire regardless of the cause; that is, wetted ignitor, gassy tube, and so forth. Using an alarm instead of shutting down and locking out allows the rectifier to continue to carry reduced load until such a time that the tube can be replaced or repaired.

The sequence for a rectifier from the time the starting impulse is received to the time that the sequence is completed is a matter of seconds. If the sequence is incomplete, indication is given quickly by the failure of the cathode circuit breaker to close. Consequently, a complete sequence check adds very little to the over-all operation, and is not required.

Mr. Siegel suggests that the conditions of high rectifier temperature, low cooling water pressure, and high temperature of the mercury vapor pump not be allowed to shut down and lock out since facilities are available to allow these conditions to be automatically corrected. It is unfortunate that Mr. Siegel did not disclose what these facilities were to enable us to comment on them. Experience has indicated that after a rectifier has been in service for a period of time, trouble occurring as a result of these three items is not of a temporary nature and is not self-corrective. The scheme suggested by Mr. Siegel would cause the rectifier to "pump" and eventually arc back and lock out.

In our paper, high rectifier temperature, low cooling water pressure, and high temperature of the mercury vapor pump results in shut-down and lockout if the rectifier has been in service for a definite period of time (usually 10 minutes), but only prevents starting for this time interval if the rectifier has been shut down due to loss of or low alternating voltage. This is done to avoid a lockout when during shut-down the latent heat of the rectifier units may operate the contacts that detect high rectifier temperature and high temperature of the mercury vapor pump, or low voltage cause the water pump motor to fail to keep sufficient water pressure. This arrangement does not allow the unit to "pump."

Mr. Siegel in questioning our omission of a statement regarding the interrupting duty required of the d-c circuit breaker during paralleling failed to note that in the first portion of our paper we stated "high-speed or semihigh-speed switching is provided for a rectifier depending on the d-c voltage, the kilowatt rating of the individual rectifier, and the full load rating of the station bus." This statement would normally be interpreted that the rating of the station bus is determined by the paralleled equipment.

Protection of Electronic Power Converters

AN AIEE COMMITTEE REPORT

THIS report discusses the protection of electronic power converters operating as power rectifiers. It treats specifically the problems of protection arising from the occurrence of faults, such as overloads and short circuits in the load circuits to which the rectifier is connected, and arc-back within the rectifier.

Electronic power converters must be provided with adequate protective gear in order to prevent damage to the various components of the rectifier unit from overload or fault currents. Protective gear also is required to limit the extent and duration of the disturbance in a-c and d-c systems at the time of fault.

The report is devoted primarily to the problem of protection of power rectifiers of the size and type usually encountered in railway, electrochemical, and general industrial applications, see American Standard ASA C34.1—1949.[1] In such rectifiers, reactance is usually the dominant factor in determining the magnitude of fault currents. Correction factors are given for resistances up to values numerically equal to the reactance.

While overvoltages and surges may occur as a result of the flow and interruption of fault currents in the rectifying elements and other parts of the rectifier circuit, they do not usually affect the problem of protection to any considerable degree. The factors to be considered and the measures required for overvoltage protection are, therefore, omitted from this report.

The report is based on the experience of manufacturers and users of electronic power converters, accumulated over many years. The material is derived from published literature, theoretical analyses, and factory and field tests. A list of references is given at the end of the report.

Historical Review

The general principles of protection of electronic power converters have not changed greatly through the years, but many improvements have been made in the character and performance of protective systems.

Early rectifiers were protected by conventional a-c and d-c switchgear of the type used on comparable rotating equipment. As the size of rectifiers and rectifier installations increased, it became necessary to increase the speed of interruption and limit the ceiling values of fault currents. These improvements have been accomplished by the use of arc suppression, anode circuit breakers, and higher transformer reactance. Arc suppression provides high-speed interruption of the fault current in the normal anodes of the rectifier. Anode circuit breakers provide fast interruption of the fault current in the faulty anode and at the same time make it possible to maintain essential service with the rest. High transformer reactance reduces the ceiling value of damaging fault currents.

Metalclad switchgear now is widely used and has improved the safety of rectifier installations. Increased speed of circuit breaker interruption has not only been a great advance in isolating faults and reducing damage to equipment but has improved service and reduced outage time. In the larger rectifier sizes, the use of anode circuit breakers has added materially to the protection of rectifiers and increased the quality of uninterrupted service to the load.

Nature of Problem

The purpose of this section is to provide a basis for analyzing the problem of protection. The basic factors which enter into this problem are formulated. The effects of the various types of faults on the rectifier unit, the a-c system, and the d-c system are qualitatively stated. The analysis of rectifier circuits under normal conditions is thoroughly covered in the references cited and a fair working knowledge is assumed.

Principles of Operation

The circuit diagram for a typical polyphase electronic power converter unit is shown in Figure 1. The unit consists of a rectifier transformer, a group of rectifier tubes, and the a-c and d-c circuit breakers. The a-c winding of the rectifier transformer is connected to the 3-phase a-c system by the a-c circuit breaker. The d-c winding is connected to the d-c system through the tubes and the d-c circuit breaker.

The rectifier transformer shown is the 6-phase double-Y, and is the most commonly used for large power rectifiers. The methods for determining fault currents outlined in this report are based on this circuit.

The operation of the electronic power converter is based on that characteristic of the mercury-arc rectifier which normally permits current flow in only one direction, namely, from the anode to the cathode.[2,3] The tubes act merely as switches and the currents are determined by the connected circuits. Current flow in any tube takes place when a positive voltage is impressed on the anode with respect to the cathode after the tube is made conductive. This is done by establishing a cathode spot on the surface of the mercury pool and applying a suit-

able potential on the grid (if present). The start of conduction may be controlled by means of either an ignitor, which starts the cathode spot, or a grid, which controls the passage of electrons to the anode, depending on the type of tube. This is known as phase-control. Once the current flow in the tube has started, it will continue until it is brought to zero by the action of the external circuit, as the grid has no influence on the current and can regain control of conduction only after it has reached zero. The resumption of current flow in succeeding cycles may be prevented by rendering the tube nonconductive by means of ignitor or grid control, or by the interruption of excitation. This action is called arc-suppression.

In the 6-phase double-Y circuit the rectifier transformer d-c winding is connected in two 3-phase groups, or wyes, with their neutral points interconnected by an interphase transformer. Each Y and the tubes connected to it constitute a commutating group which carries a direct current I_e. The two commutating groups operate in parallel, and each carries one-half of the total direct current I_d.

A graphic analysis of the circuit action is given in Figure 2, which shows the phase voltages, the direct voltage, the anode currents, and the anode-to-cathode voltages in the 6-phase double-Y circuit.[4]

Figure 2(A) shows the action under the condition of free conduction where each anode is permitted to start firing as soon as its voltage becomes positive with respect to the cathode. The direct voltage, or output voltage of the rectifier, e_d is the average of the direct voltages of the two commutating groups e_{d1} and e_{d2}. The difference between the voltage waves of the two commutating groups is shown by the shaded area. This voltage difference appears across the interphase transformer as an alternating voltage having a fundamental frequency three times that of the phase voltages.

Commutation, or current transfer, requires a definite time, or commutating angle u, which depends upon the transformer reactance and the commutating voltage, that is, the voltage difference between two commutating phases. The transformer reactance which controls the transfer of current between phases of a commutating group is called the commutating reactance. The commutating angle increases with increasing commutating reactance or increasing commutated current and decreases with increasing commutating voltage.

The anode-to-cathode voltage wave of phase R_1 is shown in Figure 2. During the conducting period, the anode is positive with respect to the cathode by the amount of the arc-drop. During the nonconducting period, the anode is negative with respect to the cathode.

Figure 2(B) shows the action with phase control. Under this condition, anode R_1 continues to carry current despite the fact that its voltage is lower than that of anode R_3. The output voltage of the rectifier may be reduced by means of phase control, the average value of the direct voltage decreasing as the angle of retard, α, is increased. The commutation process with phase control is similar to that for the free rectifier except that the commutating angle is smaller because of the increased voltage effective for commutation.

The natural voltage regulation of the rectifier unit is determined to a large degree by the commutating reactance. The effect of the overlapping conduction during commutation is to decrease the average value of the direct voltage. The direct voltage is reduced further by resistance drop in the transformer and arc-drop in the tubes. Under rated loads the inherent d-c voltage regulation curve for a rectifier unit deviates only slightly from a straight line as the commutating reactance and resistance voltage drops are linear and the arc-drop is essentially constant. The area between heavy overloads and short-circuit has not yet been fully analyzed.

The duty on the tubes is determined by the wave shapes of the anode current and the anode-to-cathode voltage. These wave shapes depend on the rectifier circuit used and operating conditions such as voltage, current, and amount of phase control.[5] A rectifying device must be a good conductor during the conducting period of each cycle and a good insulator capable of withstanding the anode-to-cathode voltage during the inverse period. The transition from a conducting to an insulating state occurs at the conclusion of each conducting period. Most arc-backs are initiated during this transition.

Figure 3. Delta 6-phase parallel double-Y connected rectifier transformer damaged by repeated arc-backs

Nature of Faults

Overload and Short Circuit. The operation of the rectifier on moderate overload is the same as at rated loads except that the commutating angle increases with increasing load current. This modifies the anode current and voltage waves and so changes the duty on the tubes.[6]

As the impedance at the d-c terminals of the rectifier approaches zero, the current delivered by the rectifier increases to a limiting value determined by the constants of the rectifier circuit. The conduction period of the tubes increases to 180 degrees or more on d-c short circuit.

The mode of operation of the rectifier circuit also changes so that the anode current waves are substantially sinusoidal instead of flat-topped.

The direct current delivered by a rectifier unit to a bolted short-circuit usually ranges from 10 to 20 times its rated current. Its magnitude is determined primarily by the reactance of the rectifier transformer and the a-c supply system.

Arc-Back. Faults may occur within the rectifier unit as the result of arc-back.[7,8] An arc-back is the failure of the rectifying action resulting in the flow of a principal electron stream in the reverse direction due to formation of a cathode spot on an anode.

When an arc-back occurs, fault current flows from the other transformer phases and their connected anodes to the faulty anode as shown by the broken arrows in Figure 1. If the d-c circuit to which the rectifier is connected has other d-c voltage sources, the current flow at the positive terminal of the rectifier will reverse and a fault current will flow from the positive terminal through the faulty tube and its transformer winding to the negative terminal as indicated by the broken arrows.

If there is no feedback from the d-c circuit and all the reverse current to the faulty anode comes from the other anodes of the rectifier, the fault current is determined only by the impedance of the transformer and a-c supply system and by the arc-drop. It usually attains its maximum value in the first cycle and its magnitude is generally comparable to that of the d-c short-circuit current.

If there is feedback from the d-c circuit into the faulty anode, the fault current is determined by the inductance and resistance of the fault path. The rate of rise of d-c fault current is determined largely by the inductance of the circuit, and its ultimate value by the circuit resistance, tube arc-drop and voltage regulation of the current source. In most rectifier installations, the circuit constants are such that the feedback current requires several cycles to reach sustained values. Ultimate fault currents of 25 to 100 times the rated current of the tube and the transformer winding to which it is connected may be obtained.

Effects of Faults on Rectifier Unit

Overloads and Short Circuits. Mercury pool tubes may usually be operated at loads above their continuous or short-time ratings without causing immediate structural failure. However, they do have definite limitations and such operation may impair them and shorten their life.

The rating of an electronic power converter usually includes overloads of specified magnitudes for specified periods of time, to take care of service requirements for particular applications. Standard overload ratings for electrochemical, industrial, and several classes of railway applications have been established.[1] Two types of overload ratings are specified: overloads of 2-hours' duration and overloads of 5-minute or 1-minute duration.

Forward currents in excess of specified overload rating, up to short-circuit values may have some or all of the following effects on the tubes of an electronic power converter:

1. *Temperature.* Temperatures of the anodes and other internal parts in the arc path will be raised by the increased losses and may be drastically increased by local heating.

2. *Vacuum.* The increased temperatures and increased ion current to the anode during the inverse period may cause the liberation of gases and impairment of the vacuum.

3. *Contamination.* The increased arc-drop voltage may start intermediate cathode spots on the metal or graphite surfaces in the arc-path or adjacent to it. Such cathode spots erode the surfaces and produce metal vapor or graphite powder, which may deposit on insulating surfaces and ultimately impair the operation of the rectifier.

4. *Surges.* If a rectifying device carries high forward current with insufficient mercury vapor to provide the needed ionization, high-voltage surges may result due to so-called "arc starvation": this might be detrimental to the insulation of the rectifier transformer, cables, wiring, or other connected equipment.[9] Such surges are likely to occur on suddenly applied overloads if the rectifier is too cold.

5. *Arc-Backs.* The occurrence of arc-back in a mercury arc rectifier is basically random in nature. However, it is influenced by the magnitudes and shapes of the current and voltage waves impressed on the anode and the conditions within the rectifier. During overloads, the probability of arc-back is increased as a result of the greater ionization produced by the overload current. It also may be increased by the physical conditions listed above.[6,7,8]

Figure 4. Bus-bar leads deflected during arc-back tests

Figure 5. D-c short-circuit, idealized conditions

The over-all effect of overloads and repeated short-circuits on the rectifier tubes is to decrease their reliability and increase the cost of maintenance. A pumped rectifier subjected to such overloads may have to be reconditioned more frequently. The operating life of sealed tube rectifiers subjected to such overloads may be shortened.

Excessive overloads will raise the operating temperature of the rectifier transformer windings above the rated temperature, which will shorten the transformer life. Too frequent application of the short-time rated overload will have the same effect. Excessive overloads also may increase the maintenance cost of the switchgear, due to overheating of circuit breaker contacts or due to an increase in the number of operations to clear faults if the frequency of faults on the rectifier is increased by the overloads.[10]

Arc-Back. Arc-backs result in forward fault currents in the normal anodes and the transformer windings connected to them, of the same order of magnitude as obtained on d-c short circuit. In addition, the faulty anode and its transformer winding carry a reverse current which considerably exceeds that incurred on d-c short circuit. The effects of arc-back currents are similar to those of short-circuit currents except for the action of the reverse current on the faulty anode. The arc-back current, if sustained too long, will cause pitting and overheating of the anode, will impair the vacuum, and may damage the anode insulator and vacuum seals.

Because of their high magnitude, the repeated occurrence of arc-backs is attended by an increasing hazard of thermal of mechanical failure of the rectifier transformer. Severe mechanical stresses are imposed on the coils, leads, and even the core. Figure 3 shows a 3,000-kw 600-volt delta-parallel double-Y rectifier transformer which was tested to destruction by the repeated application of artificial arc-backs in the laboratory. The repeated impacts caused mechanical failure of the upper coils of the a-c winding. Figure 4 illustrates the need for adequate strength and bracing in bus-bars and leads.[11]

Figure 6. Arc-back, idealized conditions

Effects of Faults on Systems

Fault currents flowing in the d-c windings of the rectifier transformer during short-circuit or arc-back are reflected in the a-c windings and supply system. There is no flywheel effect between the a-c and d-c sides, the disturbances are limited only by the impedances involved and the speed of the protective gear. D-c faults on a rectifier therefore produce all the harmful disturbances on the a-c system that would be produced by a fault of the same magnitude occurring directly on the a-c system.

Short circuits and arc-backs produce the same kind of disturbance on the connected d-c system as similar faults on other types of equipment. Flashover may result on parallel rotating equipment and sympathetic arc-backs may occur on parallel rectifiers.

Determination of Fault Currents

This section presents analyses of the circuit action during faults and outlines the procedure for the determination of fault currents. Knowledge of both the character and magnitude of fault currents is important in the selection and design of protective systems.

The complete and accurate determination of the fault currents in rectifier circuits under all conditions is not possible at the present time, as existing analyses do not cover adequately the wide variety of circuits and their many modes of operation. However, it is the object of this section of the report to describe typical circuit action during faults in rectifier circuits under usual service conditions and to present a procedure for the

approximate determination of fault currents for the double-Y circuit. A number of sample computations are given in Appendix II.

Rectifier faults may be resolved into two general types, namely, d-c short circuit and arc-back. The nature of the rectifier fault currents under idealized conditions are shown on Figures 5 and 6. During d-c short circuit, the circuit action is determined by the relative magnitude and location of the various impedances in the rectifier unit and short circuit path. Figure 5 shows three idealized cases and their equivalent circuits and wave forms. During arc-back, the circuit action is determined primarily by the number of sources of voltage producing the fault current. The action may be resolved into the three cases illustrated in Figure 6.

The equivalent circuit shown on Figure 7 indicates the various impedance elements which may be present in a typical 6-phase double-Y rectifier circuit. In the general case all of these impedances must be considered in determining fault currents. However, in actual practice, one or two of these impedances usually play a dominant role and the others may either be neglected or allowed for by a small correction. In the usual rectifier the d-c windings associated with each phase of the transformer are interlaced, the anode leads are generally short, and current limiting reactors in the anode leads are seldom used. Under these conditions all the a-c circuit reactance may be considered located in the a-c supply line.

D-C Short Circuit

The form and magnitude of the direct current obtained when a rectifier is short circuited at its load terminals determines the duty imposed on d-c circuit breakers, the forces on d-c conductors, and the possibilities of destructive damage. Of interest is the rate of rise of d-c short-circuit current, its maximum instantaneous value and the final or sustained value. Similarly, the corresponding values of the reflected fault current in the a-c system determine the duty on the a-c circuit breaker. The magnitude of the tube currents under short circuit also is important, as it determines the duty imposed on the tubes, consequently the probability of tube arc-back or damage, and the forces on transformer windings and conductors.

The circuit action in a rectifier during d-c short circuit depends upon the location of the impedance. When the circuit impedance is in the transformer primary or supply line, the fault currents are similar to those in a standard power transformer on a-c short circuit. The two anodes connected to diametrically opposite phases act as a pair and carry current alternately. With the impedance located in the transformer secondary the anodes act independently and each carries current for more than one half of the cycle. Three cases are considered in the analysis of d-c faults, namely: primary impedance only; secondary impedance only; and both primary and secondary impedance.

Figure 7. Equivalent circuit during d-c short circuit

The symbols used in the formulas which follow are defined in Appendix I. The circuit constants are defined and their determination described in the section on circuit constants.

Case I. Short Circuit With Primary Impedance Only

The following assumptions are made in the derivation of the formula which apply to a 6-phase double-Y transformer: a-c windings are perfectly interlaced (all impedance in a-c windings and supply line).

There is no impedance in anode leads (usual types of current-dividing reactors do not contribute to the impedance). There is a bolted d-c short circuit (zero resistance and inductance) and free conduction (no phase control).

Typical wave forms of the current obtained during d-c short circuit are shown in Figure 8. The anode current waves are sinusoidal and add to produce the d-c fault current.

Under sustained short circuit the two anodes connected to diametrically opposite phases fire alternately to produce symmetrical a-c flow in the a-c winding.[9,12,13] The sustained anode current is

$$i_{ss} = \frac{\sqrt{2}\,E_s}{Z_s} \text{ (crest value)} \tag{1}$$

The sustained direct current is

$$I_{ds} = \frac{2\sqrt{2}}{\pi}\frac{VA}{E_s Z_{c\,pu}} = 0.900\frac{VA}{E_s Z_{c\,pu}} \text{ (average value)} \tag{2}$$

The sustained fault current also may be expressed in terms of the rated direct current I_{dn} by

$$I_{ds} = \frac{2\sqrt{3}}{\pi}\frac{I_{dn}}{Z_{c\,pu}} = 1.10\frac{I_{dn}}{Z_{c\,pu}} \tag{3}$$

This current has a ripple whose fundamental frequency is six times the a-c supply frequency. The crest value of the sustained direct current is $\pi/3$ or 1.047 times its average value, or $2\,i_{ss}$.

The sustained supply line current is

$$I_{Ls} = \frac{I_{Ln}}{Z_{c\,pu}} = \frac{VA}{\sqrt{3}\,E_L Z_{c\,pu}} \text{ (rms value)} \tag{4}$$

On a bolted short circuit, the transient fault current will reach a peak higher than the sustained crest value during the first cycle. This peak is caused by d-c transient components in one or more anode currents.[14] This transient decreases exponentially as a function of the resistance/reactance ratio and generally has little effect beyond the first peak of the a-c wave. The ratio resistance/reactance is the sum of the equivalent resistances of the transformer, supply line, and arc-drop, to the sum of the transformer and supply line reactances, all expressed either in ohms or per-unit quantities.

A correction factor, K, a function of resistance/reactance, is applied to the sustained crest values to obtain the value of the first, or transient, peak of the anode, a-c system, and d-c fault currents. K is plotted against resistance/reactance in the curve of Figure 9. K cannot be greater than two and very seldom exceeds one and a half.

Transient peak of anode current

$$i_{sf} = K\,i_{ss} \tag{5}$$

The transient peak of supply line current

$$I_{Ls}' = \sqrt{2}\,K\,I_{Ls} \tag{6}$$

Transient peak of direct current

$$I_{ds}' = K\frac{\pi}{3}I_{ds} \tag{7}$$

The rate of rise of direct current in the fault varies with the switching angle and attains maximum value on a bolted short-circuit with no inductance. The peak I_{ds}', is reached along a composite curve in one-half to two-thirds cycles.

Figure 8 (left). Fault currents during d-c short circuit on 6-phase double-Y rectifier with primary impedance only

Figure 10 (right). Factors for determining reverse and forward current during arc-back with a-c feed only

The initial rate of rise is $\pi f I_{ds}'$ but the average rate of rise to the first major peak is $2fI_{ds}'$. Since the fastest circuit breakers available do not begin to limit the current appreciably in less than one-third cycle, it is suggested that an average value for this period be taken as

$$\frac{di}{dt_{as}} = \frac{1}{2}\sqrt{3}\,\pi f\, I_{ds}' \text{ (amperes per second, approximate)} \quad (8)$$

This formula gives reasonably accurate values of current up to 90 per cent of the peak.

Case 2. Short Circuit With Secondary Impedance Only

In this case the following assumptions are made which apply to a 6-phase double-Y transformer, with all impedance in anode leads. There is a bolted d-c short circuit (zero resistance and inductance), and free conduction (no phase control).

This is an idealized case rarely realized in practice. With no mutual impedances, each phase (anode) acts independently, carrying current more than 180 degrees as determined by circuit constants. If there are no losses, the current will flow 360 degrees in the form of a fully displaced sine-wave. A typical wave-form of the anode current is shown in Figure 5. The current in the fault is the sum of six such anode currents spaced 60 degrees apart. It is to be noted that the short-circuit current does not drop off after the first peak as in Case 1. The displacement transients that cause this peak are repeated in each cycle.

A sustained direct current, assuming no losses, is

$$I_{ds} = K\sqrt{2}\frac{VA}{E_n Z_{c\,pu}} = \frac{K\sqrt{3}\, I_{dn}}{Z_{c\,pu}} \text{ (average value; approximate)} \quad (9)$$

this value is π times that obtained for the sustained current in Case 1 with zero resistance. Theoretically, the conduction period of each anode is 360 degrees. Losses decrease the conduction period and the short-circuit current to values intermediate between those given by equation 2, and equation 9.

Figure 9 (below). Transient factor for determining crest value of transient current on d-c short circuit

Figure 11 (right). Fault current during arc-backs in 6-phase double-Y rectifier with no external d-c feed

Case 3. Short Circuit with Both Primary and Secondary Impedance

This is a general case which is encountered in practice. The analytical treatment is similar to that for Case 1 with primary impedance only except for a greater complexity of circuit action. Exact analyses for this case have not been completed.

Usually, most of the circuit reactance is in the primary, while the major part of the resistance, consisting of the transformer d-c winding, the anode leads, and the tube arc-drop, is located in the secondary. Secondary resistance must be considered in the determination of fault currents: However, since its effect on circuit action is generally small, it is permissible to transform and add it directly to the primary resistance. Fault currents are then computed as in Case 1.

Equivalent Machine Constants. In setting up a d-c system problem on a calculating board, it may be desirable to represent the rectifier as a machine having a known induced voltage, internal resistance, and inductance. For specific cases it is possible to determine and assign values based on the short-circuit currents and rate of rise as obtained above. Some work has been done along this line, but it is felt that no recommendations should be made until the subject has been explored further.

Arc-Back

An arc-back in a rectifier constitutes a short circuit of both the a-c and d-c circuits. The current in the faulty anode under arc-back conditions is the sum of the current delivered by the normal anodes of the rectifier and the current fed back from the d-c system. The currents which flow in a 6-phase double-Y rectifier during arc-back are indicated in Figure 1 by the broken arrows.

In analyzing the fault currents during arc-back, it is helpful to consider idealized cases where only one component of feed to the faulty anode is present, before proceeding to the general case where both a-c and d-c feed are present.

Case 1. Arc-Back with A-C Feed Only

This type of fault is approximated when arc-back occurs in a rectifier supplying a resistance load with no other source of d-c power in parallel. If the current contribution from the other Y is neglected, the circuit reduces to a single Y with one faulty anode carrying reverse current and two normal anodes carrying forward currents. The equivalent circuit and typical fault current wave forms are illustrated in Figure 6 (Case 1).

Two values of fault current are of particular interest. The crest reverse current in the faulty anode affects the duty on the faulted phase particularly as regards the possibility of tube damage and forces on transformer windings. The crest forward current in the normal anodes determines the probability of arc-back on those anodes.[12,13,14]

The following assumptions are made in the analysis of this case: no back feed; 6-phase double-Y transformer with only one Y contributing to the fault; saturation of transformer core neglected; free conduction (no phase control).

During arc-back with a-c feed only the crest reverse current in a faulted anode is

$$i_{sr} = \frac{K_r \sqrt{2}\, E_s}{Z_c} \tag{10}$$

and the crest forward current in normal anodes is

$$i_{sf} = \frac{K_f \sqrt{2}\, E_s}{Z_c} \tag{11}$$

Values of the reverse current factor K_r and the forward current factor, K_f, for various resistance/reactance ratios are given in Figure 10. The resistance/reactance ratio should include the resistance of the rectifier transformer and the equivalent resistance of the rectifier tube. These factors give the crest values of the fault current obtained during the first cycle when arc-back occurs immediately after forward conduction of the anode. The current may increase to some extent during subsequent cycles but sufficient information for most system studies is generally provided if the values of reverse and forward current obtained during the first cycle are known.

The fault current waves obtained in a 6-phase double-Y rectifier during arc-back with no d-c feed except that from the anodes of the normal Y are shown on Figure 11. These fault current waveforms show that the arc-back current in the faulty anode is supplied principally from the other two anodes of the same Y. The current contribution of the anodes in the normal Y is limited to a relatively low value, because of the impedance of the interphase transformer, the interlacing of the two secondary coils of each phase of the rectifier transformer, and the long conduction period of the anodes of the faulted Y. Since the anodes in the normal Y of a double-Y rectifier do not begin to feed any appreciable current into the fault until the second cycle, their contribution may be neglected without appreciable error in most cases.

Case 2. Arc-Back with D-C Feed Only

This condition is obtained in practice when all the normal anodes of the rectifier are prevented from firing at the time of the fault, as when arc-suppression is instantly applied to the faulted rectifier. It also is approximated to a limited extent if several rectifiers are connected in parallel and are supplied through a common line reactance so that the loading on the parallel rectifiers reduces the anode voltages on the faulty rectifier and thereby reduces the a-c feed from the normal anodes on the faulted Y.

The equivalent circuit for this idealized case and the waveform of the current in the faulty anode are shown in Figure 6 (Case 2).

Reverse Current. For the most severe condition when arc-back is initiated at the instant of voltage reversal[13] the instantaneous reverse current i_d in the faulty anode is given with fair accuracy by the equation

$$i_d = \left[\frac{E_d'}{R_d} - \frac{\sqrt{2}\, E_s}{Z_d}\right]\left[1 - e^{\frac{-R_d t}{L_d}}\right] + \frac{\sqrt{2}\, E_s}{Z_d} \times [1 - \cos \omega t] \tag{12}$$

The time t is measured from the beginning of the negative half cycle of a-c voltage wave.

The reverse current attains peak values at the end of the first, third, fifth, and succeeding half cycles. The crest value at the nth peak is

$$i_d = \left[\frac{E_d'}{R_d} - \frac{\sqrt{2}\, E_s}{Z_d}\right]\left[1 - e^{\frac{-R_d}{L_d f}\left(n - \frac{1}{2}\right)}\right] + \frac{2\sqrt{2}\, E_s}{Z_d} \tag{13}$$

Case 3. Arc-Back with Both A-C and D-C Feed

The case of arc-back with both a-c and d-c feed is the one most commonly met in practice. It is obtained whenever arc back occurs among parallel rectifiers or in a rectifier supplying a counter-electromotive-force load.[14,15] Figure 12 shows the fault currents obtained on a 6-phase double-Y rectifier during arc-back with both a-c and d-c feed. The circuit action is quite complex and a complete solution including the current contribution of all the normal anodes has not been made. However, several approximate methods for determining the fault currents have been developed.

Method 1. The analysis of the fault currents during arc-back with both a-c and d-c feed is simplified by representing the faulted Y as a simple 3-phase rectifier and treating the action as a combination

Figure 12 (left). Fault currents during arc-back with both a-c and d-c feed in a 6-phase double-Y rectifier

Figure 14 (right). Circuit action during arc-back with both a-c and d-c feed in 3-phase Y rectifier

of a-c feed from the two normal anodes and d-c feed from a single source consisting of all other anodes and parallel sources. The equivalent circuit is shown in Figure 13 together with all the circuit impedances which are considered in the analysis. The inductance of the d-c circuit external to the rectifier, including the inductance of the source of feed-back, the inductance of the d-c leads and the "air-core" inductance of one-half the interphase transformer (where the rectifier circuit includes one) is represented by L_{d1}. R_{d1} represents the corresponding resistance. L_c and R_c are the commutating inductance and resistance per phase. R_c includes the arc-drop resistance.

For purposes of defining the circuit action, the time during a cycle is divided into four intervals corresponding to the different current flow patterns obtained during the successive conduction periods of the two normal anodes. The dotted lines in Figure 13 indicate the components of the currents which flow in the circuit during the interval when anode 2 is conductive. The circuit action and the waveforms of the transient currents in the faulty anode, the normal anodes, and the d-c feed obtained in a typical example are shown in Figure 14. In this example, the action is that obtained during the first cycle when the arc-back occurs at the end of conduction and it is assumed that the rectifier is operating without phase control so the anodes are free to conduct at any time. The current in subsequent cycles may be obtained by dividing them similarly into four intervals and assuming larger currents in the faulty anode at the beginning of each cycle. This step-by-step method of analysis also may be used where the initial conditions are different and phase control is applied.

Method 2. The foregoing analysis illustrates a method of attack that can be applied to obtain results of good accuracy. However, it is too cumbersome for general use and a more practical solution may be obtained by assuming that the circuit action is equivalent if one normal anode in the Y is assumed to feed into the arc-back throughout the entire cycle. The a-c voltage effective in the d-c circuit is then $1/2\ E_e$ and the equivalent resistance and reactance are $1/2\ R_e$ and $1/2\ X_e$ since the feedback flows through two phases in parallel. The procedure is then as follows:

1. Calculate the normal and faulty anode currents for arc-back with a-c feed only as in Case I.
2. Calculate the current for arc-back with d-c feed only as in Case 2, using $1/2\ E_e$, $1/2\ R_e$, and $1/2\ X_e$.
3. Add one-half of the d-c feed (step 2) to current calculated for the faulty anode in step 1, and subtract 1/2 from the normal anode current.

Method 3. For many problems it is sufficient to know the ceiling values of the fault currents. These may be determined by the following rules:

1. The current in the normal phases will never exceed that obtained with a-c feed only, as given in Case 1.
2. The current from the d-c source generally will not exceed that obtained with d-c feed only, as given in Case 2, unless sympathetic arc-backs occur in additional anodes. The d-c switchgear should interrupt the feedback before this occurs.
3. The current in the faulty anode cannot, in the usual case, exceed the sum of the maximum current in one normal phase and the maximum feedback.

It should be recognized that the values estimated by this method are ceiling values and will exceed those obtained in practice.

Added Circuit Effects

The procedure for calculating rectifier fault current which has been outlined involves many simplifying assumptions which are not fully realized in practice. Two of the more important factors which must be considered are the characteristics of the feedback source and the effects of phase control.

Effect of Feedback Source. The characteristics of the source of d-c feedback affect both the transient and sustained currents obtained during arc-back. The following discussion covers some of the important cases:

Double-Y Circuit. The analysis for Case 3 covers the action in a single Y. The normal Y of a double-Y rectifier is treated as a source of d-c feed. As stated in Case 1, the amount of d-c feed from the normal Y is limited by the coupling between the transformer windings in the normal and faulted wyes and also by the inductance of the interphase transformer. At the initiation of the fault, the build-up of current from other sources of d-c feed is delayed until the interphase transformer becomes saturated. The time required for such saturation to become effective depends on the design of the interphase transformer, the rectifier load at time of arc-back, and the phase of arc-back. Usual values range up to 80 degrees at supply line frequency.

Motor Load. The reactance of a general purpose motor load is generally high compared with the reactance of the rectifier transformer windings. In such cases, the a-c components of current in the d-c circuit may be neglected and the current may be calculated by assuming the motor to be short circuited at its terminals by series inductance and resistance equal to one-half of the inductance and resistance of one d-c winding of the rectifier transformer, this being a close approximation of the average inductance and resistance in the fault circuit over the entire cycle.

Parallel Rectifiers. When two or more rectifiers are operated in parallel and one of them arc-backs, the inductance of the d-c circuit feeding the fault is of the same order of magnitude as the inductance of the transformer windings in the fault. In such cases, the amplitude of the a-c component of d-c fault current is considerable and may not be neglected. This observation also applies in the case of a rectifier supplying low-inductance motors such as machines with pole face windings.

Effect of Phase Control

The effect of phase control on the fault currents is neglected in the foregoing analyses. It is assumed that the anodes are free to conduct at any time. This assumption is usually justified in the determination of fault currents in connection with the problem of protection as it gives maximum or ceiling values. While the rectifier anodes are not free to conduct at all times in most rectifiers, because of the nature and characteristics of the excitation circuits, conduction is usually not limited sufficiently to greatly reduce the fault current. When a double-Y rectifier is operated with free conduction, anode current flow starts at the 30 degree point of the voltage wave. Under short-circuit conditions, conduction is retarded so that the phase angle of conduction is $\tan^{-1} X/R$. As excitation is usually maintained for an appreciable part of the cycle, the anodes actually operate without phase control during the short circuit. Under arc-back conditions, the feed from the normal anodes may be reduced somewhat by phase retard.

Other Circuits

The general analytical procedure which has been outlined for the double-Y circuit may be used in the determination of fault currents in other rectifier circuits. The large variety of circuits and circuit parameters precludes a comprehensive treatment at the present time.

Circuit Constants

When making fault current calculations, it is essential that the proper values of circuit reactance, resistance, and impedance be used. The circuit data which are usually available are reviewed and the procedure for determining the equivalent circuit constants from these data is described.

Circuit Data

Transformer Constants. Factory tests on rectifier transformers usually provide the following information:[1]

The per cent impedance of the rectifier transformer is stated on its nameplate. It is determined in the usual manner by short-circuiting the total d-c winding and

is calculated on the basis of rated volt-amperes (VA) of the rectifier transformer at the a-c terminals.

The value of the commutating reactance of the rectifier transformer in ohms referred to the d-c winding also is given on the transformer nameplate. It is determined by short circuiting the total a-c winding and applying a sinusoidal voltage between two terminals of the d-c winding where commutation occurs. See ASA C-34.1-1949, section 5.304.

Load losses (P_r) and the resistances of the windings, including the interphase transformer, are usually measured during factory tests and may be obtained from the manufacturer.

Typical values of commutating impedances and resistance/reactance ratios (for the transformer only) as encountered in practice are given in Table I. They vary widely and should be used for estimating purposes only.

Supply Line Constants. The resistance and reactance of the supply line are usually expressed in per cent on a nominal kilovolt-ampere base. They also may be given in ohms per line. When no other information is available the minimum reactance of the supply line may be estimated from the interrupting rating of the a-c circuit breaker.

The supply line impedance may range from a fraction of 1 per cent to 10 per cent based on the rectifier transformer rating and rarely exceeds the latter value.

Rectifier Constants. The rectifier arc-drop is generally unimportant in short circuits but may have considerable effect on arc-back currents, particularly below 600 volts. The arc-drop varies with the type of tube, the relative current magnitude, current wave shape, direction of current flow, and other factors. In some cases it is nearly constant over a considerable current range and in others it varies directly with instantaneous current.

In making fault current calculations, arc-drop may be represented as either an equivalent resistance, a counter electromotive force, or a combination of both. The choice of method depends upon the accuracy desired, the fidelity with which a particular arc-drop may be represented, and mathematical convenience. In general, arc-drop is most readily represented by an equivalent resistance which may be added directly to the other resistance elements in the rectifier circuit.

It is not possible to give concise data on arc-drop at fault current values for the various types of rectifier tubes because of the meager data available at the present time. However, test data on one type of sealed tube give an equivalent resistance of 0.0015 to 0.0025 ohm. Data on one type of pumped tank give an equivalent resistance of 0.002 to 0.004 ohm.[14,15]

Table I. Typical Values of Constants for 6-Phase Double-Y Rectifier Transformers

Application	Voltage, D-C Volts	Type of Tube	Size of Unit, Kw	Z_{epu}	R/X
General industrial	250	Sealed	75–500	0.055–0.10	0.19–0.39
General industrial	250	Pumped	500–1,500	0.04–0.08	0.15–0.43
Railway class I	275	Sealed	200–500	0.06–0.10	0.19–0.26
General industrial	600	Pumped	1,000–3,000	0.05–0.08	0.13–0.28
Electrochemical	600	Pumped	1,000–3,000	0.05–0.09	0.11–0.28
Railway class II and III	600	Pumped	1,000–3,000	0.05–0.08	0.13–0.28

Notes:—The above values apply for a-c line voltages of 550 volts to 66 kv in ratings up to 1,500 kw and 6.6 kv to 66 kv in higher ratings.

The values of impedance are somewhat higher at voltages above 22 kv than at lower voltages.

The ratio of per-unit commutating reactance to the per-unit 3-phase short-circuit reactance usually ranges from 1.02 to 1.10.

Load System Constants. The resistance and inductance of the load system is determined from the constants of the parallel rectifiers, rotating machines and other voltage sources and of the connecting leads. Each parallel rectifier may be represented as an equivalent machine consisting of a voltage source with series resistance and inductance. The other voltage sources may be represented in a similar manner. Generally a d-c system consisting of several parallel voltage sources may be represented by a single large equivalent machine. The regulation of the d-c system may be entered into the computations as an equivalent series resistance.

Equivalent Circuit Constants

The equations for determining the fault currents have been derived on the basis of equivalent circuits with lumped constants. To use them, the impedances of the various elements must be added to obtain total values.

It is frequently necessary to convert impedance values from ohms to per unit and vice versa. The following equation gives the relations between ohmic and per-unit values of reactance in 3-phase circuits

$$X = \frac{E_L^2}{VA} X_{pu} = \frac{3E_a^2}{VA} X_{pu} \tag{14}$$

Similar expression may be written for resistance and impedance.

Total Commutating Reactance in Ohms

The total commutating reactance is the sum of the reactances of the transformer, supply line and other elements in the a-c circuit. To determine its value in ohms referred to the d-c winding proceed as follows:

1. Obtain ohmic value of commutating reactance of rectifier transformer from its nameplate. If it is not known, an approximate value may be determined from equation 14 using the 3-phase impedance Z_{pu} as the per-unit reactance.

2. Determine the ohmic value of the supply reactance X_L. If the supply line reactance is given in per-unit X_{Lpu} referred to a nominal volt-ampere base VA_1, the ohmic value may be determined from equation 14. If no other information is available the minimum reactance of the supply line may be estimated from the interrupting rating of the a-c circuit breaker by the relation:

$$X_L = \frac{E_L^2}{VA_{brr}} \tag{15}$$

3. Transform the ohmic value of supply line reactance to ohms referred to the rectifier transformer d-c winding by the transformation formula

$$X_{cL} = \left(\frac{E_a^2}{E_a}\right) X_L \tag{16}$$

4. Add the ohmic values determined in 1, and 3 to obtain X_c.

Total Commutating Reactance in Per Unit

All per-unit quantities are based on the rated volt-amperes VA input to the rectifier transformer a-c terminals. To determine the per-unit values, X_{pu}, corresponding to the ohmic values, X, divide the ohmic values by the value of unit reactance

$$\frac{3E_a^2}{VA}$$

which results in

$$X_{pu} = \frac{VA}{3E_a^2} X \tag{17}$$

Total Resistance

The total resistance of the a-c circuit is the sum of the effective resistances of the transformer and supply line and the equivalent resistance of the rectifier. Since the resistance of the rectifier tubes may exceed that of the transformer windings the total per-unit resistance must be

calculated in order to determine the resistance/reactance ratio.

The per-unit resistance of the transformer may be calculated by the equation

$$R_{pu} = \frac{P_r}{VA} \tag{18}$$

The equivalent per-unit resistance of the rectifier tube may be determined from its equivalent ohmic resistance by the relation

$$R_{epu} = \frac{VA}{3E_a^2} R_a \tag{19}$$

Total Commutating Impedance

The total commutating impedance of the rectifier transformer, rectifier, and supply line in either ohmic or per-unit values may be determined by vector addition of total resistance and reactance.

Protective Systems

Essentially, the protective system of an electronic converter is designed to protect the converter against the harmful effects of faults occurring within the unit and without. For obvious reasons the switch gear employed for this purpose also is used to accomplish normal switching functions, and other features are added to prevent operation under improper conditions that might endanger the equipment or personnel. This section of the report discusses the various factors entering into the selection, design and operation of the protective system and equipment.

Functions of the Switchgear

The protective switchgear for an electronic power converter must perform two basic functions: limit the duty on the rectifier so as to prevent damage from overloads and faults; and limit the disturbance in the a-c and d-c systems during faults.

Ideally, in order to protect the rectifier, transformer, and other parts of the rectifier unit, the protective switchgear must function to limit:

1. The duration of overloads and the frequency of application of rated overloads; the desired action may be obtained by interrupting the rectifier a-c or d-c circuits, reducing the rectifier output voltage by phase control, or other means.

2. The duration of d-c short circuit or the magnitude of the short circuit currents; this may be accomplished by interruption of the a-c or d-c circuit, arc-suppression of the rectifier, insertion of resistance in the d-c circuit, application of phase control to the rectifier, or similar means.

Figure 16. Single-line diagram of main protective system

3. The duration and magnitude of arc-back currents.[17,18] The current flow to the faulty anode must be completely interrupted. This requires the interruption of both the feedback from the d-c circuit and feed from the a-c circuit. The feedback current from the d-c circuit can be interrupted by interrupting any part of the circuit through which this current flows or by removing the sources of d-c voltage. The current flowing to the faulted anode from the other anodes of the rectifier can be interrupted by removing their phase voltages, or making them nonconductive by means of arc-suppression. The arc-back current arising from both the d-c circuit and the other anodes also may be interrupted by opening only the circuit of the faculty tube.

In order to limit and minimize the disturbance in the supply and load circuits, the protective switchgear must perform several functions in addition to those required for the specific protection of the rectifier unit. First, it must have suitable sensitivity and speed of interruption to obtain selective circuit breaker operation and limit the extent of the system disturbance. Second, it must provide backup protection in the event of failure of a protective device or circuit which might endanger equipment or personnel. For some applications it must be adaptable to automatic control with provisions for load resistance measurement, automatic reclosure, and similar features. The various functions must be co-ordinated so as to obtain a definite planned behavior for a large variety of circumstances.

Elements of Protective System

The protective system of an electronic converter includes all devices required in the installation to interrupt fault currents together with the relays that actuate them, as well as those components of the converter and connected systems whose inherent characteristics serve to limit the magnitude or rate-of-rise of fault current. Also for the purpose of the report, the protective system will include elements provided to protect the unit against improper operating conditions, as well as protection against overloads which do not reach fault proportions. All the elements shown on Figure 16 are considered a part of the protective system, and may be used in various combinations to effect the desired results. The main protective elements may be divided into two general classes; one class being those devices which protect by interrupting or preventing current flow, and the other being those which limit the current flow by virtue of their impedance. Referring to Figure 16, the elements in the first class are:

1. The a-c circuit breaker, which interrupts the a-c circuit *52*.

2. The anode circuit breaker, used in the anode circuits to interrupt both the a-c and d-c circuits on arc-back *7*.

3. The d-c circuit breaker which interrupts the d-c circuit *72*.

4. The rectifier, which, when controlled by suitable arc-suppression devices, can interrupt the flow of forward current.

The elements in the second class are:

1. The impedance of the supply source.

2. The transformer impedance.

3. The inductance and resistance of the d-c circuit, which limit the rate of rise and maximum value of short circuit and feedback currents.

Classes of Protective Systems

In order to classify the various arrangements of protective schemes, the following classes are suggested for adoption and use. They are based on the time of current limitation and point of circuit interruption when faults occur due to short circuits and arc-backs.

Five general classes are proposed (see Figure 17):

Class I—Interruption at the a-c and d-c terminals of the unit with medium-speed a-c and d-c circuit breakers.

Class II—Interruption at the a-c and d-c terminals of the unit with medium-speed a-c

circuit breaker, and high-speed d-c circuit breaker.

Class III—Interruption within the unit by the use of medium-speed anode circuit breakers.

Class IV—Interruption within the unit by the use of high-speed anode circuit breakers.

Class V—Interruption within the unit by the use of arc-suppression.

Class I is the simplest and oldest form of protective system. It is used widely for all types of service on small and medium size units, particularly in transportation, mining, and general industrial applications. It also is used extensively in large isolated units when fault currents are limited.

Class II is used when higher speed interruption of the d-c feed back circuit is required than is provided by the medium-speed d-c circuit breaker. It is used for large kilowatt rated units as well as on the higher d-c voltages—1,500- and 3,000-volt classes, for transportation service. It provides an economical protective means when rapid interruption is required to prevent the tripping of other units in parallel. In some cases, arc-suppression also is included to reduce the duty on the transformers and a-c circuit breaker as well as to lessen the disturbance to the a-c system. D-c reactors also may be provided to reduce the rate of rise of feedback current from the d-c system.

Class III provides an economical protection system for small and medium size units connected to high-voltage a-c systems. A few applications have been made in mining and transportation services. Additional protection is required for the transformer in the form of fuses or remote feeder circuit breakers.

Class IV usually is adapted to large-capacity units when maximum protection of rectifier and rectifier-transformer from damaging over-current is required. It is used in essential service applications when continuity of power flow is required. Typical applications include large electrochemical, transportation, and heavy industrial installations. It also is used for electronic exciters of large generators. Additional a-c and d-c circuit breakers are provided either as part of the unit, or in the a-c and d-c systems in order to obtain necessary operational features as required.

Class V utilizes arc-suppression for interrupting short circuit and arc-back currents in applications having no d-c feedback. The usual applications are rectifiers in service where high d-c voltages are used to supply resistance-type loads such as frequency changers and radio plate supplies. Backup protection must be provided by a circuit breaker in the a-c supply line. When the d-c system can feed reverse current to a rectifier during arc-back, a high-speed cathode circuit breaker is required.

The above classification is based on the following definitions:

Semihigh-Speed Cathode Circuit Breaker. A semihigh-speed cathode circuit breaker is one which will interrupt a circuit in 0.03 to 0.05 second after the initiation of fault current.

High-Speed Circuit Breaker. A high-speed cathode or anode circuit breaker is one which will start current reduction within 0.017 second after initiation of fault current.

Rectifier Unit. A rectifier unit is a unit comprising a single rectifier transformer and the rectifier sections connected to it, together with the associated switchgear.

Selection of Protective System

The selection of the protective system for electronic converters is based on the grade and character of performance required and the capabilities and limitations of the converters, transformers and, protective devices which are available. The characteristics and capabilities of the various elements of the protective system must be co-ordinated to obtain the operation desired in a sound and economical manner.

Minimum interrupting ratings of the switchgear are determined by the fault current calculations developed in the section on Determination of Fault Currents of this report. However, switchgear must protect itself as well as the converter unit. To do so, it must be capable of interrupting the maximum fault that can develop across its own terminals. Any other scheme must be used with great caution. Here we will discuss additional factors which must be considered in the selection of protective devices, and the preparation of specifications.

Service Requirements

The basic protective requirements for a rectifier unit are satisfied by protective gear consisting of an a-c circuit breaker and a d-c circuit breaker. The a-c circuit breaker is relayed to trip on time delay for the lower values of overcurrent and instantaneous for higher values of overcurrent. The d-c circuit breaker is tripped by instantaneous reverse current. Such equipment is adequate for most applications of a single unit of moderate capacity, where protection of the converter equipment is the prime consideration. These minimum requirements may be satisfied by a-c circuit breakers having opening speeds up to eight cycles (at 60 cycles) and d-c circuit breakers with interrupting speeds of three to five cycles. A large number of installations of this type have been made, and are in successful operation. Longer interrupting times are very undesirable, and good practice favors shorter times. Good practice has thus established this minimum equipment on the basis of apparatus which is available in standard manufacture, and is in use for protecting other types of electric generating and load equipment.

The selection of switchgear with other features should be based on the need for meeting further service requirements or providing additional protection for the rectifier unit to obtain the most economical arrangement. Where single units are installed and short-time outages are not objectionable, minimum protective gear consisting of a-c and d-c circuit breakers is adequate. Where continuity of d-c

Figure 17. Single-line diagram of the five classes of protective systems

power flow is essential, anode circuit breakers capable of opening and automatically reclosing only the faulty anode circuits and maintaining power flow on the normal anode circuits are required. Some rectifier units are constructed with two rectifier sections operating from a common transformer. At the time of arc-back, the faulty section is cleared by means of an anode circuit breaker so that power flow is maintained on the normal section.

Where two or more rectifiers operate in parallel in essential service applications, it is desirable that d-c power flow to the load be maintained during arc-back. This requirement makes it necessary at the time of arc-back to clear the faulty rectifier before the overload on the parallel units causes them to arc-back. This requirement may be met by the use of suitable high-speed circuit breakers.

Rectifier Limitations

The characteristics of the rectifier tubes limit the overload and fault currents which can be permitted. The overload capacities of rectifier tubes are determined by thermal overload, fault current limit, control limit, and damage currents.

The thermal overload limit of the pool-type tube determines what overloads can be carried for longer than momentary swings. This allowable load is usually sufficiently above the thermal overload limits of the transformer so that the protective relay settings can be set just slightly above the guaranteed 2-hour rated overload. On 600 volts and higher, the tubes usually arc-back before the thermal limit is reached.

The fault current limit is the maximum current which a tube is able to conduct for one cycle without arc-back. If this limit is exceeded on the normal anodes during arc-back, sympathetic arc-backs will occur and the fault will be extended.

The control limit is the value of current which causes the tube to fail to control. This limit must not be exceeded where arc-suppression is to be used.

The damage currents at which the internal parts of tubes are damaged is usually so high that such currents are not the limiting factor in determining the overload ratings of the rectifier unit.

Ordinarily, it can be assumed on low-voltage, pumped, single-anode tubes that the tube characteristics do not determine the permissible overload or fault currents as long as the other rectifier equipment is protected. However, on sealed tubes, the short time overload capacity is lower and the tube characteristics determine the permissible overloads. This limit is usually slightly above the rated overloads. On some sealed tubes, the fault current must be limited to prevent structural damage to the tubes and on some high-voltage tubes, the current must be limited to allow arc suppression.

Transformer Limitations

In selecting the protective equipment for a rectifier installation, the transformer overload capacity must be considered since usually the transformer is designed for exactly the ratings of the installation. The protective equipment should be adjusted to remove the load from the rectifier if the current and time interval exceed the rated values. The life of the transformer is reduced by the overtemperatures so produced.

The ratio of fault-to-rated current in the windings during arc-back is higher than for normally applied power transformers in other services. The maximum fault current which rectifier transformer windings can withstand without failure due to structural deformation is an important factor in the design of protective systems. Allowance also must be made for the effect of repetitive faults in causing hammering and wear of coil insulation.

Circuit Breaker Requirements

Switchgear for rectifier equipment must be capable of reliable operation with low maintenance despite a relatively high frequency of faults.

Some of the factors which will determine the selection of the proper switchgear devices are listed below:

A-C Circuit Breaker

1. Voltage and frequency of the a-c system.
2. The supply line current at the 2-hour rating of the rectifier.
3. Maximum fault current which the a-c system can deliver with a fault or short-circuit applied on the load side of the circuit breaker.
4. Interrupting time.
5. Derating factors due to reclosing requirements and frequency of operation.
6. Atmospheric conditions and altitude.

D-C Circuit Breaker

1. The d-c voltage rating of the rectifier unit.
2. The two-hour current rating of rectifier unit.
3. Maximum fault current delivered by the rectifier on d-c short circuit, or maximum feedback current which the d-c system can deliver at the time of arc-back, whichever is greater.
4. Current limiting and interrupting time.
5. Frequency of operation.
6. Atmospheric conditions and altitude.

Anode Circuit Breaker

1. The d-c voltage rating of rectifier unit.
2. The secondary current at the 2-hour rating of rectifier.
3. Maximum half-cycle fault current delivered by both a-c and d-c system during arc-back.
4. Interrupting time.
5. Rectifier circuit, and type of transformer connection.
6. Atmospheric conditions and altitude.

Protective Relaying

Overload

The ideal overload protective system would disconnect the converter whenever the magnitude or duration of an overload exceeded the values specified in the rating of the converter. This cannot be fully accomplished by means of overload and timing relays commercially available, and neither the cost nor complexity of the devices required for such protection have been found justified.

Inverse time overload relays afford protection only above the short-time (one or five minute) rating of the machine, and commercially available thermal overload relays afford protection only above the 2-hour rating. Since the 2-hour rating is seldom used except during emergencies, a compromise setting of the thermal relay is usually adopted or the relay is omitted.

Transformer overtemperature and hot-spot indicators give some added measure of protection to the transformer on the 2-hour rating. The rectifier has too short a thermal time constant to be effectively protected by the transformer overtemperature indicator.

Fault Detection

Fault-current detection is provided by means of external relays or built-in devices. For tripping primary a-c circuit breakers, at least in the larger ratings, use is generally made of separate overcurrent relays connected to current transformers. These relays are usually a combination of inverse time and instantaneous elements.

Primary voltages of 600 volts or less permit the use of low-voltage air circuit breakers, which will normally have built-in direct-acting trip attachments. Separate inverse-time relays may be used for purpose of selectivity.

Anode circuit breakers have reverse current (in some cases, an overcurrent series trip) coil built into each pole. Most anode circuit breakers today employ flux-shifting type tripping devices which

are connected for reverse current tripping to afford protection on arc-back.

Primary circuit overcurrent relays might be used to trip anode circuit breakers but the individual series trips on each pole of the circuit breaker should be retained if the advantage of this type of circuit breaker on arc-back is to be realized.

There is a high fault-to-normal current ratio occurring in the faulted anode circuit during arc-back. This ratio is between 25 to 50, in most cases, and may exceed 50.

The selection of the d-c machine circuit breaker depends on the presence of other protective devices.

Selectivity

To insure the maximum protection without sacrificing continuity of service, the protective system must possess a high degree of selectivity. Faults can be generally classified as internal and external. In the ordinary converter installation, the most common internal fault is the arc-back. External faults are usually short circuits of various degrees on the connected d-c system or internal faults in parallel units. The protective system is designed to differentiate between internal and external faults.

For a unit operating alone, the a-c system currents during an arc-back or a solid d-c short circuit are of the same order of magnitude. Selectivity between a-c circuit breaker and d-c feeder circuit breakers is obtained by the use of inverse time and instantaneous overcurrent tripping. In general, the more units there are operating in parallel, the easier it is to obtain good selectivity since each unit will contribute less to an external fault or a fault in one of the other units.

Since the arc-back is the most damaging fault to which converters are liable, instantaneous overcurrent devices (when used) are set as low as operating conditions will permit. The inrush current of the rectifier transformer is generally the limiting factor. Selectivity is lost, however, when the d-c fault results in an alternating current exceeding the setting of the instantaneous overcurrent devices, causing the a-c circuit breaker to trip. In some cases, such tripping may be avoided by the use of special inverse time overcurrent relays with just enough time delay to permit the d-c feeder circuit breaker to trip and yet not permit excessive damage to the tube elements.

As explained previously, arc-backs are most easily recognized by reverse current devices in the anode circuits. Converters equipped with anode circuit breakers, therefore, possess a very high degree of selectivity.

In the absence of the anode circuit breaker and where the d-c system produces feedback during arc-back, the reverse current trip on the d-c circuit breaker can often be utilized to provide excellent selectivity. If the reverse current tripping of the d-c circuit breaker is arranged to trip the a-c circuit breaker, fast clearing of the arc-back is obtained.

Selectivity can be obtained by means of arc-suppression initiated by an arc-back detecting device in the anode or cathode circuit. The anode circuit provides most rapid response and a positive signal in all cases, but requires a multiplicity of devices. The cathode circuit is, therefore, frequently preferred where operating conditions permit.

Tripping Means

The power source for tripping the circuit breakers of a rectifier installation must be completely reliable and the circuits so arranged that this power will always be available when the rectifier is in service. Lacking this reliability, arrangements must be made to trip all circuit breakers and disconnect the rectifier whenever the voltage of the tripping power source drops below the minimum safe operating value for any of the trip coils.

In large important installations station batteries are available for operating the circuit breakers, or at least for tripping service. Such batteries, properly maintained, have been found sufficiently reliable.

In smaller installations, particularly in small industrial plants, building service and coal mines, battery maintenance is not, in general, up to the required standard and it is better to use some other source of tripping power. For low-voltage circuit breakers under 600 volts, the safest protection is afforded by built-in direct acting overload trips. When direct-acting overload relays on the a-c circuit breaker are not desirable, current transformer trip coils normally shunted out by normally closed contacts of overload relays, provide a very reliable tripping means. Shunt or undervoltage a-c trip coils then are used for control switching operations of the a-c and d-c circuit breakers.

A-c shunt trip coils can be used with overload relays, but the circuit breaker must be provided with an undervoltage trip device. Both the shunt and undervoltage coils must be connected to the same power source. They must be so designed and adjusted that the low-voltage operating limit of the shunt trip is less than the drop-out voltage of the undervoltage device by a safe margin. An arc-back or severe short circuit may depress the voltage of the a-c power source below the minimum required to operate the shunt trip, and the undervoltage trip must then drop out, or the rectifier unit will be severely damaged.

Capacitance tripping devices have been used, consisting of a condenser charged through a small metal-plate rectifier. The charged condenser supplies the required tripping power. This system involves several vulnerable components and must be adequately protected or backed up.

Circuit Breaker and Relay Settings

A-C Overcurrent

1. Time Delay Element *51:* Set only high enough so that d-c feeder circuit breakers, or d-c rectifier circuit breaker if there are no feeders, will trip first on d-c overloads or short circuits. Usual setting is just slightly above short-time rating of the rectifier and for as short a time as the service will permit.

2. Instantaneous Element *50:* Set only high enough to over-ride the transformer inrush current. The lower it can be set, the better the protection afforded against arc-back and transformer fault.

Note:—Random arc-backs may occur when there is nothing wrong with any part of the equipment. One circuit breaker reclosure will restore service quickly in that event. Should the circuit breaker trip out again immediately due to some type of permanent fault, a second reclosure might result in further damage. Only one automatic reclosure is recommended.

D-C Overcurrent

1. D-c Overloads and Faults: Where d-c feeder circuit breakers are used either the overcurrent trip is omitted or time delay tripping is used on the rectifier d-c circuit breaker. When there are no d-c feeders, an overcurrent device *76* is provided on the rectifier d-c circuit breaker, except for electrolytic service. Device *76* should be set between the 2-hour and short-time ratings of the rectifier, as low as service requirements will permit. When d-c overload protection is omitted or set too high, the unit will be cleared by the a-c circuit breaker through the operation of *51*.

2. Feeders: When a fault or overload occurs on a distribution d-c feeder, the feeder circuit breaker is caused to

trip by an instantaneous tripping device, *176*, affording selectivity and maintaining uninterrupted service on unaffected feeder circuits. In railway, mining, and some industrial services, reclosing systems automatically restore normal service to feeders as soon as the trouble is cleared.

Reverse Current (Arc-Back)

1. Reverse Current: Under normal operating conditions, reverse current in a rectifier is not possible. In case of arc-back, most installations are capable of furnishing considerable reverse current and the cathode circuit breaker is equipped with a reverse current tripping device *32*. Where anode circuit breakers are used, the reverse current trip on the cathode circuit breaker is usually omitted. When there is no source of reverse current and no anode circuit breaker, the a-c overcurrent relays *50* are used for arc-back protection. Reverse currents above approximately 15 per cent of normal output will trip the cathode circuit breaker.

2. Anode Circuit Breakers: In installations employing high-speed anode circuit breakers, individual pole tripping is employed in many cases, eliminating service interruptions to the load. Since opening the anode lead, in case of arc-back, interrupts the a-c as well as the d-c fault path, the short-time opening of the individual pole may be followed by a successful reclosing and return to normal service. In such cases, it is unnecessary and undesirable to open the a-c and cathode circuit breakers. High-speed anode circuit breakers are usually equipped with built-in tripping means designed to trip on reverse currents less than rating.

3. Arc-Suppression: In some heavy-duty installations when no anode circuit breakers are used, methods of high-speed arc-suppression on all tubes are used to prevent the unfaulted tubes from feeding current into the arc-back. High-speed devices (half-cycle operation or better on basis of 60 cycles) are essential for satisfactory operation. Back-up protection is desirable.

Thermal (Long-Time Overload) Protection

1. Transformer: Thermal protection for the transformer is provided by a thermal relay or thermostat whose setting depends on the transformer design. Some transformers, particularly the air-cooled variety, are equipped with temperature detecting coils. Additional transformer protection may be obtained by a replica thermal relay operating from current transformers.

2. Rectifier: Thermal protection of the rectifier provides protection against inadequate cooling rather than overloading. Protection is obtained by a thermostat set in accordance with the manufacturer's recommendations.

Undervoltage Protection

1. Incoming Line: To protect the ignition circuits and all a-c closing devices and motors, a polyphase reverse phase sequence and undervoltage relay may be used *47*. This is usually set to permit starting if there is 95 per cent of normal voltage available, and to take the equipment out of service in case the voltage drops to 85 per cent or below. (A short-time delay is used here to prevent tripping on momentary voltage dips.)

2. Excitation Circuits: Should excitation fail on one or more tubes and not re-establish within a given time, the rectifier unit is taken out of service or an alarm is sounded.

3. D-C Circuit: A voltage relay *80* is connected between the positive and the negative terminals of heavy-duty pumped rectifiers. Relay *80*, when energized, permits the cathode circuit breaker to close. In starting, the failure of the cathode circuit breaker to close within a given time will lock the rectifier unit out of service by means of device *48*.

Other Protective Devices

1. Rectifier: In addition to thermal protection mentioned previously, protection is provided, as required, against low water pressure *63W*, overtemperature *26R*, and undertemperature *26L* of the rectifier, and poor vacuum *63V*. Where used, the settings of these devices should follow the manufacturer's recommendations.

2. Grounding of D-C Structures: In services 301 volts direct current and above and when one side of the d-c circuit is grounded, it is recommended that the d-c structure (metal housing or supporting metal framework) be grounded through a protective relay *64*.

3. Light Load Resistor: Where interphase transformer windings are used and low loads (not enough to excite the windings) are possible, some means of preventing abnormally high d-c voltages are desirable. The protection often takes the form, in the smaller sizes, of a permanently connected resistor across the d-c end of the rectifier but, in larger installations, the resistor is commonly switched in and out of service as required.

4. Regenerative Resistor: Some installations supply loads which may be regenerative in character, such as cranes, machine shops, elevators, rotating machines, and railways. When the system cannot absorb this regenerated power, resistors of suitable capacity are usually automatically connected across the d-c bus and disconnected after the regeneration has ceased.

Auxiliaries

1. Excitation Circuits: Protection is usually provided for ignitor misfire (which may result from faulty circuits or ignitors).

2. Protection of Auxiliaries: For pumped tubes, the mercury pump is protected by a thermostat. All auxiliary circuits, such as firing or excitation circuits, water pumps, oil pumps, vacuum pumps, fans, and water heaters, have their energizing contactors protected by thermal trip elements.

Appendix I. Nomenclature

The symbols which appear in the equations are defined as follows:

α = phase control angle of retard
u = commutation angle of overlap
$\omega = 2\pi f$, where f = frequency of a-c power system
E_a = arc-drop voltage
E_d = average d-c voltage under load
E_d' = average voltage of d-c source during feedback
E_L = a-c system line-to-line voltage in rms volts
E_m = a-c system line-to-neutral voltage in rms volts
E_s = transformer d-c winding line-to-neutral voltage in rms volts
i_d = instantaneous direct current
i_{sf} = crest forward anode current in amperes—first half-cycle
i_{ss} = crest forward anode current in amperes—sustained
i_{sr} = crest reverse current in amperes—first half-cycle
I_d = d-c load current of the rectifier in average amperes
I_{ds} = rated direct current of rectifier
I_{ds} = sustained short circuit current in average amperes
I_{ds}' = crest short-circuit current in amperes during transient period
I_{La} = rated current in rms amperes at a-c terminals of rectifier transformer at rated volt-amperes
I_{La} = sustained short-circuit current in rms amperes at a-c terminals of rectifier transformer
K = transient factor
K_f = forward current factor
K_r = reverse current factor
L_d = total inductance in henrys, of fault path during d-c feedback
P_r = rectifier transformer resistance loss in watts
R_a = equivalent resistance of rectifier arc-drop in ohms
R_c = commutating resistance in ohms per phase

Table II

Circuit Element	R, Ohms	L, Henrys
Supply line $R=0.0031\times1.042$	0.00334	
$L=0.025\times1.042/377$		69.1×10^{-6}
Rectifier transformer $(3707/230\times1,000)$ 1.042	0.0168	
$0.0575\times1.042/377$		159.0
Interphase transformer	0.0016	
Estimated inductance, fully saturated		15.8
Anode cable	0.003	
Rectifier tube arc-drop (Not included—arc-back simulated by switch)		
D-C cable	0.0034	79.5
D-C motor	0.0170	46.0
Total	0.0450	369.4×10^{-6}

R_d = total resistance in ohms of fault path during d-c feedback

t = time in seconds measured from beginning of the negative half-cycle of a-c voltage wave

X = reactance in ohms

X_s = commutating reactance in ohms per d-c winding phase

X_{sL} = commutating reactance of a-c supply line in ohms referred to the d-c winding of the rectifier transformer

X_L = reactance of a-c supply line in ohms per line

VA = rated volt-amperes of rectifier transformer at terminals of a-c winding

VA_{bkr} = circuit breaker interrupting rating in volt-amperes

Z_s = commutating impedance in ohms per phase

Z_d = total impedance in ohms of fault path during d-c feedback

Note: Per-unit quantities are indicated by subscript "pu," for example: X_{pu}, X_{spu}, Z_{spu}, and so forth. They are usually based on the primary rating, VA, of the rectifier transformer.

Appendix II. Examples of Fault Current Calculations

The procedure for calculating rectifier fault currents is illustrated by the following examples. These calculations apply to a 6-phase, 200-kw 300-volt sealed ignitron rectifier unit operating in a power circuit with constants as given in Figure 15. Tests results are given for comparison.

D-C Short Circuit

For calculating the impedances the per-unit base is 230 kva.

$$\text{Unit Impedance}=\frac{3E_s^2}{VA}=\frac{3\times283^2}{230\times1000}=1.042 \quad \text{ohms}$$

The sustained direct current is

$$I_{d3}=0.9\times\frac{VA}{E_sZ_{c\,pu}}=\frac{0.9\times230\times1000}{283\times0.0860}=8,500 \quad \text{amperes (average value)}$$

The transient direct current = ratio $R/X=0.0243/0.0825=0.295$. From Figure 9 $K_p=1.41$.

$$I_{d3}'=1.41\times\frac{\pi}{3}\times I_{d3}=12,500 \quad \text{amperes (crest value)}$$

Tests show the fault currents obtained during d-c short circuit with a bolted short. The comparative values are:

	Calc., Amperes	Test, Amperes
Average sustained current	8,500	7,700
Crest transient current	12,500	11,000

Arc-Back With A-C Feed Only

The calculated per-unit impedances are the same as for d-c short circuit except that the resistance of the interphase is omitted since no current flows in it and the resistance of the tube is assumed to have two-thirds value since a switch was used to simulate the faulty tube. The total per-unit impedances are then

$R=0.0226$ $X_{pu}=0.0825$ and $Z_{c\,pu}=0.0855$

The ohmic value of commutating impedance is

$$Z_c=\frac{3E_s^2}{VA}.Z_{c\,pu}=1.042\times0.0855=0.0890 \quad \text{ohm}$$

The ratio $R/X=0.0226/0.0825=0.274$. From Figure 9, $K_r=1.61$ and $K_f=1.35$.

Crest reverse current is

Circuit Element	R_{pu}	X_{pu}
Supply line (for values see power circuit diagram)	0.0031	0.0250
Rectifier transformer $X_{s\,pu}=X_s/1.042=0.060/1.042$		0.0575
$R_{pu}=P_r/VA=3,707/230\times1,000$	0.0161	
Interphase transformer $R_{pu}=P_i/3\,VA=346/3\times230\times1,000$	0.0008	
Anode cables $R_{pu}=0.003/1.042$	0.0029	
Rectifier tubes (arc-drop) $R_{pu}=0.0015/1.042$	0.0014	
Total	0.0243	0.0825

$$\text{Total } Z_{c\,pu}=\sqrt{R_{pu}^2+X_{pu}^2}=0.0860$$

$$i_{sr}'=K_r\frac{\sqrt{2}E_s}{Z_c}=\frac{1.61\times\sqrt{2}\times283}{0.089}=7,220 \quad \text{amperes}$$

The crest forward current

$$i_{sf}'=K_f\frac{\sqrt{2}\,E_s}{Z_c}=6,230 \text{ amperes}$$

The comparative values of the fault current with a-c feed only with the rectifier operating on only three anodes are:

	Calc., Amperes	Test, Amperes
Crest reverse current (faulty anode)	7,220	7,440
Crest forward current (normal anodes)	6,230	6,370

Arc-Back With D-C Feed Only

In calculating the fault current in this case, the total ohmic resistance and the total inductance are determined by adding the values for the various elements in the d-c fault path. The calculated impedances are shown in Table II.

The total impedances are then

$R_d=0.0450$

$X_d=L=377\times369.4\times10^{-6}=0.139$ ohm

$Z_d=\sqrt{R^2+X^2}=0.146$

Ratio $R_d/X_d=0.324$ ratio $R_d/L_d=121.6$

The approximate values of current in the faulty anode at the successive peaks at the end of the first, third, and fifth half-cycles are given by the equation

$$i_d'=\left[\frac{E_d'}{R_d}-\frac{\sqrt{2}\,E_s}{Z_d}\right]\left[1-\epsilon^{-\frac{R_d}{L_d}\frac{1}{f}\left(n-\frac{1}{2}\right)}\right]+\frac{2\sqrt{2}\,E_s}{Z_d}$$

Substituting

$$\frac{E_d'}{R_d}=\frac{2,800}{0.045}=6,230 \text{ amperes}$$

$$\frac{\sqrt{2}\,E_s}{Z_d}=\frac{2\times283}{0.146}=2,740 \text{ amperes}$$

The approximate currents in the faulty anode at the end of the first, third, and fifth half-cycles are shown in Table III.

Table III

Cycle $(n-1/2)$	$\left[1-\epsilon^{-\frac{R_d}{L_d}\frac{1}{f}\left(n-\frac{1}{2}\right)}\right]$	Current i_d', Amperes
1/2	0.632	7,680
1 1/2	0.950	8,790
2 1/2	0.995	8,960

No test results were obtained for this condition. It is included here to illustrate the method.

Arc-Back With Both A-C and D-C Feed

If it is assumed that on the average, two phases are conducting and that the average

Table IV

Circuit Element	R, Ohms	L, Henrys
Supply line 0.5×0.00324	0.00162	
$0.5\times69.1\times10^{-6}$		34.5×10^{-6}
Rectifier transformer 0.5×0.0168	0.0084	
$0.5\times159.0\times10^{-6}$		79.5
Interphase transformer	0.0016	15.8
Rectifier tube arc-drop (Not included—arc-drop simulated by switch)		
Anode cable 0.5×0.003	0.0015	
D-C cable	0.0034	79.5
D-C motor	0.0170	46.0
Total	0.03352	255.3×10^{-6}

Table V

Cycle $(n-1/2)$	Currents in Amperes: D-C Source	Currents in Amperes: Faulty Anode
$^1/_2$	7,280	10,860
$1^1/_2$	9,960	12,000
$2^1/_2$	10,340	12,200

Table VI

	Calc., Amperes	Test, Amperes
Reverse current in faulty anode		
At end of 1st half cycle	10,660	8,680
At end of 3rd half cycle	12,000	12,300
At end of 5th half cycle	12,200	12,900
Maximum d-c feedback	6,230*	7,030

* Value calculated for arc-back with d-c feed only.

a-c voltage in the circuit is one-half E_a, then the impedances of the circuit are shown in Table IV.

The total impedances are

$$R_d=0.0335 \text{ ohm} \quad X_d=L=377\times255.3\times10^{-6}=0.096 \text{ ohm}$$

$$Z_d=\sqrt{R^2+X^2}=0.101 \text{ ohm}$$

Ratio $R_d/X_d=0.348$ $R_d/L_d=131.4$

Substituting in the equation used in the previous section, gives the approximate currents in the d-c source at the end of the first, third, and fifth half cycles. Note that $E_a/2$ is used in making the calculation. The approximate current in the faulty anode is obtained by adding half of the current in the d-c source to the value of current in the faulty anode for arc-back with a-c feed only (See section on Arc-Back With A-C Feed Only). These values are shown in Table V.

$$\frac{E_d'}{R_d}=\frac{280}{0.0335}=8{,}400 \text{ amperes}$$

$$\frac{\sqrt{2}\,E_d}{2\,Z_d}=\frac{\sqrt{2}\times283}{2\times0.101}=1{,}980 \text{ amperes}$$

The effect of the time taken for saturation of the interphase transformer was not considered in the calculation and the calculated value of current for the first half cycle is, therefore, too high. Comparative values are shown in Table VI.

No Discussion

Selection and Application of Power Transformers

HOWARD P. SEELYE
FELLOW AIEE

THE CHOICE of a power transformer for use on a power system is governed quite largely by the characteristics of that system, the precedents set by previous purchases, and the established standards of the industry. It follows, therefore, that any discussion of the selection of transformers must deal to a considerable extent with the matter of standards, both those for the individual company and those for the country as a whole. This paper will, therefore, take up several of the more important features of power transformers with particular attention to the relation between the needs of the operating system and some of the standardization activities now in progress.

Standardization

Power transformers have been standardized to a considerable degree for many years. These standards have been developed and improved continuously. Recently, however, there has been a strongly directed effort toward the revision and extension of these standards on a national industry-wide basis. The Joint Edison Electric Institute-National Electrical Manufacturers Association Committee completed its work and published its report on Preferred Voltage Ratings for A-C Systems and Equipment[1] in May 1949, including therein proposed voltage ratings for power transformers. The Subcommittee on Standardization of Power and Distribution Transformers of the American Standards Association Sectional Committee on Transformers (C-57) is now actively engaged in working on standards for the various features of these transformers, including the application of the preferred voltage ratings. The author of this paper has been closely connected with both of these activities.

The major problem for those who are setting up standards is to determine those items and details which will best fulfill the wishes and the real needs (these may not be synonymous) of the greatest majority. The problem of the user is first to participate in the formulation of the standards to the extent of having his ideas and practices fully considered, and thereafter to find means, if possible, for adopting the established standards for his own purposes and thereby join the majority in getting the price savings which should result.

The chief purpose of standardization is, of course, reduction in cost. This is accomplished mostly by a reduction of varieties, and a concentration on the most advantageous types, the increased volume in these allowing economies in production, distribution, and stocking. To realize this objective, standards adopted should be as broad and flexible as feasible in order to cover the real needs of the greatest possible number of users. Furthermore, they should not be so restrictive as to stifle further improvement and development in design and practice. In a field such as power transformers, where a considerable variety in the requirements of the users is well established, it is obviously impossible to set up standards which will be universally acceptable. If, however, a standard corresponds with the existing practice of a fair majority of the users, there will be some of the users who can adopt it by minor changes in their ideas, and who will be induced to do so if they can thereby gain a cost advantage. There will, of course, be certain systems which will not find it practical to use a standard without changes in their practice, which would outweigh any possible saving. Sometimes users in this latter class will complain that they are being penalized if standards are not set up in accordance with their particular needs. They should recognize, however, that a real standard cannot be effected merely by committee action but only by the concerted agreement of a number of users.

It is to be hoped that the new standards for power transformers can be established on a broad enough basis so that those users, who find it impossible to accept all of the features of the complete standard units, can still partake to some extent in the advantages by using standard features and parts as far as allowable under their own restricting conditions. If standardization is properly effected, the over-all result should be a tangible saving in cost not only to those who can conform with the standard but also to those who cannot fully conform. The cost of unavoidable "specials" should, on the other hand, not be greater, because of the existence of standards, than they would be if there were no such standardization.

Voltage Ratings

The voltage ratings for power transformers proposed by the Joint EEI-NEMA Committee on Preferred Voltage Ratings were the result of extensive studies of the ratings and operating voltages existing in the industry. Practice in this regard is considerably confused because of the fact that previous ratings corresponded with voltages used during the period of progress from multiples of 110 volts, to 115, 120, and 125 volts, with numerous variations thereof. A transformer is, however, essentially a ratio device. A transformer which will step down from 23,000 to 2,300 volts will

Paper 50-134, recommended by the AIEE Transformers Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 13, 1950; made available for printing April 7, 1950.

HOWARD P. SEELYE is with the Detroit Edison Company, Detroit, Mich.

** From reference 1.

also step down from 24,000 to 2,400 volts, or from 25,000 to 2,500 volts provided other characteristics are suitable. It was naturally impossible for the committee to arrive at standards which would match exactly all of the variety of ratios in use. The choice was made, therefore, to fit as closely as possible to the predominating historical ratios, with the belief that these could be adopted without undue penalty by most of those whose customary ratios were similar, although differing somewhat numerically.

The surveys indicated that, in general, a total range of taps of approximately 15 per cent on the high-voltage side of the transformer is needed in the industry. It appeared, however, that this whole range is not required by a large enough portion of the users to warrant the expense of including it in a single standard—the majority would be penalized for the advantage of the few. Most of the applications can be divided into two distinct groups. In one of these, either the high-side voltage is relatively low or a comparatively high voltage is desired on the low side for general distribution circuits, both of these conditions needing transformer ratios in the lower part of the total range mentioned. In the other group, a higher range of ratios is required for locations where the high-side voltage is relatively high or where a lower order of low-side voltage is preferred, as is the case for many industrial plants.

Two alternative designs, therefore, seemed to be the most economical answer. High-voltage ratings and taps would be exactly the same for both. Low-voltage ratings would be 2,520 for one group and 2,400 volts for the other (or multiples thereof). The nominal voltage designation of a transformer would correspond to the "preferred nominal system voltage," 34.5 kv for example. The rating upon which performance characteristics of the transformer should be specified would, however, for convenience be made the mid-point of the tap range, which may or may not be the same as the nominal voltage designation. In selecting the actual tap voltages, prevailing practice was taken into account and also the desirability of covering as fully and adequately as possible the full range of operating voltages indicated by the surveys. The steps between taps were, for simplicity and consistency, made in even voltage amounts rather than in percentages of some rating.

It is hoped and expected that most users will find either one or the other (or both) of the alternatives adaptable to their needs, their choice being based on ratios rather than specific tap-rating figures. Table I shows, for a 34.5-kv transformer, the various ratios provided by the taps on these alternative designs, and how these ratios compare with those for previous designs having taps of $2^1/_2$ per cent on 33,000 volts.

Figure 1 indicates graphically the various voltages on both high-voltage and low-voltage sides which may be obtained with these ratios, within the usual operating range of voltages for 34.5-kv and 2,400-volt systems (the "tolerable zone" of the Preferred Voltage report). The group-I (2,520-volt) design will produce 2,520 volts from 32,600 to 36,200 volts on the high side, and will also give 2,400 volts for applied voltage as low as 31,000. On the other hand, a group-II transformer (2,400-volt) will put out 2,400 volts from 32,600 to 36,200 volts applied, and will also give 2,500 volts from 33,900 to 37,000 on the high side. It is recognized that the losses for a 2,520-volt transformer will not be the same when producing full kilovolt-amperage at 2,400 volts as they might be in a transformer designed for 2,400 volts with the same high voltage applied—copper loss will be higher and core loss lower. It is believed, however, that the practical difference will not be great and will be outweighed by the cost advantages of standardization.

As an example of adaptation of the preferred voltage recommendations, on the Detroit Edison system a full tap range of 15 per cent for the system as a whole has been utilized in the past, being obtained by a secondary tap in the transformers in most cases. It is anticipated that in the future transformers can be used from group I for those units located where transmission voltage tends to be in the lower part of the system spread, and from group II for those where the transmission voltage is generally higher. The 23-kv (nominal) "preferred" tap voltages appear suitable except for certain uses where a variation of 40 kv is needed.

The ASA C57 Subcommittee previously mentioned is now in process of fitting the preferred voltage ratings to standard kilovolt-ampere ratings, and for 3-phase transformers to the phase connections—delta or wye—most commonly required. All of the various possible voltage ratings will, of course, not be included in all sizes and all phase connections. The recognized standards should be selected as only those which have sufficient demand to allow savings by quantity production. Others may be considered allowable variations or special designs according to the degree of their departure from the standards.

Kilovolt-Ampere Ratings

On any one system, it is desirable for simplicity and economy to standardize on as few kilovolt-ampere ratings as feasible. In the past, the standard ratings offered by the manufacturers have been in steps which were unnecessarily small for an individual user. These ratings for 3-phase transformers, with the steps between them in per cent of the lower rating of each step, are shown in Table II. It seems probable that for national standards the number of ratings can be reduced, resulting in appreciable economy in manufacture by concentrating on fewer sizes. The problem, which is being studied by the ASA C57 Subcommittee,

Figure 1. Preferred voltage ratings for 34.5-kv transformers

is to discover the most generally acceptable series of steps and ratings. The Detroit Edison Company has, for example, used for many years a step of approximately 60 per cent between sizes, shown in Table II. Although this series is quite consistent as to size of steps and has been found entirely practical, it is recognized that the 4,000-kva and 6,000-kva ratings are not largely used by other companies, and some intermediate sizes may be more generally favored. The last columns in Table II show another series which has been proposed. It would seem obvious that some such simplification would lead to worth-while savings and would justify a serious attempt by users to compromise on the fewer ratings.

Table II. Three-Phase Power-Transformer Kilovolt-Ampere Ratings

Present Ratings		Detroit Edison Ratings		Proposed Ratings	
Kva	% Step	Kva	% Step	Kva	% Step

Oil Preservation

Modern practice calls for the exclusion of air from free access to the oil in a power transformer because of its deteriorating action on the oil. This exclusion is accomplished in several different ways. The objectives of the design in each of these is, in addition to excluding the air, to avoid excessive positive or negative pressures within the tank throughout the probable range of temperatures produced by the transformer's operation.

The simplest method is the sealed-tank design in which the tank is completely sealed with a cushioning space of proper proportions above the oil or in an auxiliary gas expansion tank. This space is filled initially with nitrogen or with air from which the oxygen will be eventually absorbed by the oil. This design was formerly limited to the smaller sizes of transformers but has more recently been extended to larger ones. Its simplicity commends it for all sizes for which it can be justified by design, tests, and experience. It has been used successfully on the Detroit Edison system for ratings up to 30,000 kva. The "gas oil seal" design is an available alternate to the sealed tank using an auxiliary tank on the manometer principle.

For larger transformers, the "gas pressure regulated" system, the "conservator system," and also the "gas oil seal" design have been usual practice. The first maintains a positive gas pressure in the tank from a separate inert gas source. The "conservator" employs an auxiliary oil tank to keep the transformer tank full of oil under positive pressure. The "gas pressure regulated" system or "gas oil seal" system are favored by those who wish to avoid a head of oil above the top of the tank.

Noise

The present NEMA standard for noise levels for power transformers was developed about 1939. It was based on reasonably good practice at that time, although it was felt by some users that transformers could and should be built with lower noise levels than the standards allowed.

The changes introduced in materials and designs in recent years, while producing marked improvement in other directions, have seemed to tend toward more noise.

From the user's standpoint, noise from transformers frequently means greater cost for installation. As residential loads become larger and more concentrated, it becomes necessary to put larger and larger transformers in densely populated areas in close proximity to residences. On the Detroit Edison system, several 10,000-kva units are located in substations in residential districts, and two 60,000/100,000-kva transformers were recently installed in a substation in such an area. When the noise level is low enough, say, 60 decibels or less, it is probable that a transformer without special screening will not be found objectionable in such a location. If the noise is higher than this, some means to screen or enclose the noise source may be required. Up to about 75 decibels, wall enclosures, open at the top, have been used satisfactorily. For the higher levels, complete enclosure with the attendant complication of ventilation is likely to be necessary. Although there are many locations away from residences where transformer noise, even of a relatively high level, is not objectionable, nevertheless when a transformer is bought for general system use, the possibility that it may be installed in one of the more critical locations cannot be ignored. It is very desirable that all practical means for reducing transformer noise levels be developed as a means of minimizing the trouble and expense which the users must incur in their application.

Figure 2. Water-spray cooling of transformer

Transformer Loading

The load-temperature characteristics of a transformer have a direct bearing on the economy of its application and operation. For the most effective use of capacity, the loading should be related to

operating temperatures. The latter are a function of not only the kilovolt-amperes carried, but also ambient temperatures and duration of load, that is, the characteristics of the load curve. In Detroit Edison practice, the allowable load on a substation is, in general, that which can be carried by the transformers in the station without overheating, either day-to-day or when the largest one is out of service because of a failure. The temperature criterion used for emergency loading is that which will produce a loss of one per cent of the life of the insulation under the emergency loading over one daily peak load period. Load characteristics, prevailing ambient temperatures, and individual transformer characteristics are taken into account in the calculations developed for the purpose from well-known published methods.

A typical example of such a case would be a substation with two 6,000-kva transformers serving a residential and commercial load. With self-cooled units, the maximum allowable emergency load for one of these might be 150 per cent of the name-plate rating of the unit, or 9,000 kva. Supplementary cooling by fans can increase this considerably. A simple water spray, such as that shown in Figure 2, is very effective in certain cases in increasing the emergency rating, up to perhaps 12,000 kva for the case cited, where such an increase is not limited by allowable voltage or other conditions. Such a spray is not very desirable if used regularly, however, so where a day-to-day loading above the self-cooled capability is anticipated, fan cooling is preferable.

Forced oil cooling has been increasing in popularity because of its relatively low cost as compared with self-cooled designs. Usually water cooling for the heat exchanger is cheaper than fan cooling where adequate and economical cooling water is readily available, but the advantage can be easily offset by any considerable amount of piping or cost for water. Forced oil cooled transformers are best suited to attended stations where the continuous operation of pumps and fans is under immediate supervision, and to applications where the loading is more or less fixed and not subject to the large increases in emergency, which were described in the foregoing example. Although some over-name-plate capability is available for short times, they do not offer the opportunity for increasing this capability by supplementary means, which is inherent in the self-cooled unit.

Other Features

There are numerous other features which must be considered in the choice of a transformer for a specific case—impedance, losses, insulation strength, bushings, accessories, details of construction, and other factors. The standardization program which has been mentioned includes those upon which a consensus of opinion seems feasible and for which such concentration is likely to have a material influence on the cost of transformer production. The individual user's chief objective in selecting his transformer is, naturally, to promote good service and economy on his own system. It may well be that his conditions are such that established standards are not acceptable or that the higher cost of a nonstandard unit is entirely justified by savings accomplished otherwise by its use. As a rule, however, most users will derive appreciable eventual benefit from the existence of sound and comprehensive standards in the industry. Such standards can only be accomplished by the willing and understanding co-operation of all users and manufacturers in their preparation and in their use thereafter to the fullest practicable extent in the choice of transformers to be purchased.

No Discussion

Long-Distance Power Transmission

S. B. CRARY
FELLOW AIEE

THIS paper presents the results of recent studies to determine the performance characteristics of long-distance transmission systems. The analysis is directed toward a consideration of straightaway transmission systems of 600 miles in length, a distance which is representative of transmission now under study and actual development.[1,2,3] The system characteristics and requirements for economic transmission outlined in this paper may be used to furnish a guide for the future development of long-distance as well as moderate-distance transmission systems.

The first part of the paper is devoted to straightaway transmission of 600 miles and considers the effect of intermediate switching stations, series-capacitor compensation, intermediate synchronous condenser and shunt capacitor compensation, fault switching times, excitation system characteristics, and generator and receiving system reactances and inertias.

The second part gives consideration to this same distance, but with intermediate generation. Long-distance power transmission systems of the order of 600 miles may have intermediate generation which can provide a point for interconnection.[1,2] To determine the effect of intermediate generation on the over-all transmission of power it was assumed that this generation or system capacity exists at the halfway point. Several general conclusions can be drawn from these results, which may be used to indicate an expected trend in the development of such long-distance transmission systems.

Although the paper is confined mostly to the determination of stability characteristics, an indication is given of the relative economics for the various methods of increasing the power limits.

Paper 50-135, recommended by the AIEE Transmission and Distribution Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 14, 1950; made available for printing April 7, 1950.

S. B. CRARY is with the General Electric Company, Schenectady, N. Y.

The author wishes to acknowledge the assistance of the Network Analyzer and Differential Analyzer staffs of the General Electric Company and in particular the contributions of his associates: Charles Concordia; L. K. Kirchmayer; F. J. Maginniss; G. M. Miller; L. W. Robbins; and M. W. Sheets.

Summary of Results

From the results of this analysis of 600-mile transmission, the following summary can be made. The first two points are essentially a reaffirmation of previous studies.[2,4,5,6]

1. Intermediate switching stations constitute a very effective and practical way to increase the transmission-line loadings and reduce the cost of transmission.

2. Special means to overcome the stability limitations (commonly called "compensation means") are also necessary to reduce the cost of long-distance straightaway transmission.

3. Series capacitors may be used as a basis for evaluating quite accurately the expected cost of long-distance transmission.

4. Other methods of compensation such as intermediate synchronous condensers and controlled shunt capacitors may be comparable in cost to that of series capacitors. Their application will depend upon the particular system under consideration and particularly on the amount of intermediate loading.

5. Interconnection to intermediate system capacity is an entirely practical and economic method to increase the power limits of long-distance transmission systems. When such intermediate capacity already exists this means may constitute the most economic method of attaining low transmission costs.

6. A measure of the transmission-system economy is the design loading of the circuits. There appears to be no longer any justification for design or maximum loadings below the surge impedance loading for any circuit, even for the circuits with lengths as great as 600 miles and even when the system is required to withstand the loss of any one transmission line section.

7. The higher voltages, 287 kv and 360 kv, with their high kilowatt loadings for optimum economy, will be essentially limited in their use for delivery of power to large integrated systems capable of absorbing large blocks of power, such as 400 to 800 megawatts per pair of circuits. (See Table I).

8. With the continued growth, development, and interconnection of electric systems, the ability to absorb large blocks of transmitted energy is increasing.

9. Comparisons of a-c transmission with other methods of transmitting energy long distances should be persistently reappraised in view of the continued progress in the transmission art and the development of electric systems.

Discussion of Results

The following gives the results of some of the studies which have been made recently of long-distance transmission systems. These results are selected to present the information used to arrive at the foregoing summary which bears most directly on the development of long-distance power transmission systems. The first part of these results is confined to straightaway transmission at a distance of 600 miles. In the second part the results obtained with mid-point generation are discussed.

I. 600-Mile Transmission Without Intermediate Generation or Load

1. Comparison of 200-Mile and 600-Mile Straightaway Transmission System Power Limits. Figure 2 gives the results of differential analyzer studies of the power limit of 200-mile, Figure 2(A), and 600-mile, Figure 2(B), transmission systems. These studies were made for a double-circuit system with an intermediate switching station every 100 miles. The system used for Figure 2 and Figure 8 is shown in Figure 1 except that for the case of Figure 2(A) the transmission is limited to 200 miles rather than 600 miles as shown, and the series capacitors (indicated by the dotted lines) were used only for the case of Figure 8. The

Figure 1. The 600-mile transmission system

All quantities expressed in per unit are on a kilowatt and kilovolt-ampere base of $5(kv)^2$; for a 287-kv transmission system this corresponds to 412,000 kw and 412,000 kva. The system constants are

Generator:
- $x_d = 0.63$ per unit
- $x_q = 0.42$ per unit
- $x_d' = 0.21$ per unit
- $H_g = 5$ seconds
- $T_{do} = 5$ seconds

Transformer:
- $x = 0.10$ per unit

Line:
- $x = 0.8$ ohm per mile per line
- $r = 0.12$ ohm per mile per line
- $y = 5.2 \times 10^{-6}$ mhos per mile per line

System:
- $x_m = 0.2$ per unit (includes receiving end transformer reactance)
- $H_s = 50$ seconds

Regulating System:
- $\mu_1 = 20$
- $\mu_2 = 4$
- $T_e = 0.47$ sec. for 200-mile line
- $= 0.93$ sec. for 600-mile line
- $E_{max}' = +2.25$ per unit regulator limits
- $E_{min}' = -0.30$ per unit regulator limits

System Damping:

Torque Coefficients	Fault On	Fault Cleared
T_{d1s}	1	4
T_{d2s}	0	3
T_{d3s}	0	3
T_{d4s}	15	18

results of Figure 2 are for an uncompensated line or $x_c = 0$. The differential analyzer method of analysis is described in reference 7. Figure 2 shows the effect of fault-clearing time on the power limit, where the power limit is given in per unit sending end power on a $5 \times kv^2$ base. For example, per unit power for a 287-kv system is $5 \times (287)^2$ or 412,000 kw. See Table I.

The results shown can be interpreted directly for any single conductor per phase circuit from Table I which gives the per unit kilowatts and kilovolt-amperes for the higher voltages. If dual conductors are used, then the per unit power and kilovolt-amperes will be increased approximately 25 per cent.[8] Accordingly, the results given in this paper can be interpreted also for dual conductors per phase although all the results are given directly for single conductors per phase.

As shown in Figure 2(A) for the 200-mile line the power limit for 0.06 second fault-clearing time and an exciter time constant of 0.68 second (per unit response of approximately unity) is 1.065 in per unit or 440,000 kw for a 287-kv system (692,000 kw for a 360 kv system and, if 360 kv with dual conductors, 866,000 kw). This represents a fairly good loading for a double-circuit 200-mile system. Figure 2(B) for the 600-mile uncompensated line ($x_c = 0$) with the same amount of connected generation as for the 200-mile system has a power limit equal to 0.735 per unit or 303,000 kw for the 287-kv system. Therefore, the 600-mile line has a power limit of only 69 per cent of

Table 1

Circuit (kv)	Per Unit kw and kva* $[5(kv)^2]$
360	650,000**
287	412,000
230	264,000
161	130,000
115	66,000
69	24,000

*This column corresponds to the total surge impedance kilowatt loading of two circuits when each circuit has a surge impedance of 400 ohms.

**If a dual conductor[1,8] is used, then the per unit kilowattage is increased approximately 25 per cent above the values shown so that at 360 kv the per unit power becomes 813,000 kw.

Figure 2. Sending-end power versus fault-clearing time for stability

Three-phase fault at sending end. Illustrating effect of excitation system time constant. Intermediate switching station every 100 miles. See Figure 1 for system

A. 200-mile line B. 600-mile line

Figure 3. Effect of intermediate switching station on transient stability limit for 600- mile transmission system similar to that of Figure 5 with exception that number of intermediate switching stations was varied and series and shunt compensation was not used

$V_R = V_S = 1.0$; $H_g = 5.0$; $H_m = \infty$; $x_g = 0.30$; $x_m = 0.25$; per unit power and kilovolt-amperes $= 5(\text{kv})^2$; fault clearing time $= 0.05$ second

the 200-mile line, other conditions being kept constant. It should be noted that this comparison is on the basis of the same sending-end reactance for each case, or for the same equivalent generation. If the generation had been reduced correspondingly to the reduced limit for the 600-mile case, in order to maintain the same per unit reactance per kilovolt-ampere of generating capacity, the power-limit difference between 200- and 600-mile lines would have been increased. In making this study, the per unit generator kilowatts are assumed to be $5 \times \text{kv}^2$ which is about the economic loading for a 600-mile double-circuit line (single conductor per phase) corresponding to 1.0 per unit power generation. It is believed that this is a satisfactory method of making such a study as variations from the basic study can be easily made for different amounts of generation or variations in machine reactance.

The object of the subsequent analysis will be to determine the methods by which the power limit for the 600-mile straightaway line may be increased from a value of about 70 per cent to at least 100 per cent of its surge impedance loading for two lines.

2. Effect of Intermediate Switching Station. In the above comparison of 200- versus 600-mile transmission, the results are presented for the case of using intermediate switching stations every 100 miles, as this was considered to be in the region of the most economic number of intermediate switching stations.

Figure 3 shows how the power limit increases with increasing number of switching stations. For this case the system shown in Figure 5 was used, assuming an equivalent voltage behind transient reactance (x_d') and a total fault duration of three cycles. It can be readily seen that for the case of the 600-mile line the number of intermediate stations appreciably increases the power limit. The power limit using five intermediate switching stations, as contrasted with none, more than doubles the power limit, increasing the received power limit from 0.30 to 0.65 per unit or from 124,000 to 268,000 kw for a 287-kv system.

Assume that the transmission line costs $30,000 per circuit mile for a 287-kv system, $36,000,000 for the two circuits; and the transmission line circuit breaker positions cost $200,000 per switch position, a total of $800,000 for four circuit breakers when no intermediate stations are used and $4,800,000 for 24 circuit breakers when five intermediate stations are used.

Then the cost per kilowatt for the transmission, not including the terminal transformers and their circuit breakers, is $36,800,000/124,000 kw = $297 per kilowatt, with no intermediate switching stations and $40,800,000/268,000 kw = $152 per kilowatt, with five intermediate switching stations. This fully demonstrates the value of intermediate switching stations.

This result is not surprising as it is well known that the use of intermediate switching stations is an economical means to increase the reliable power limit of high-voltage transmission systems.[3,4] In this study intermediate stations were assumed to be spaced every 100 miles. For a double-circuit line it may be economical to space them even closer. However, this was thought to be close enough to the optimum spacing particularly when there will usually be the practical future possibility of adding an additional parallel circuit in the normal development of a transmission system. The next step in this example is to further reduce the cost of transmission below $152 per kilowatt for this 287-kv case.

3. Series Capacitor Compensation. Figure 4 shows the increase in transient power limit with increased series capacitor compensation. Per cent series compensation is taken in this paper to mean the per

Figure 4. Transient stability limit of 600-mile line, per unit power generated and received as a function of per unit series capacitor compensation; five intermediate switching stations; see Figure 5 for system

$V_S = 1.05$; $x_g = 0.30$; $x_m = 0.25$; $V_R = 0.95$; $H_g = 5.0$; $H_m = \infty$; per unit power and kilovolt-amperes $= 5(\text{kv})^2$; shunt reactor compensation equal to series-capacitor compensation so that at normal frequency the surge impedance of the compensated line is 400 ohms. Fault-clearing time is 0.05 second. Capacitor reinsertion time is assumed to be zero

Figure 5. System diagram

cent compensation of the reactance of the line, that is, for a 600-mile double-circuit line with 0.8 ohm reactance per mile, 75 per cent compensation distributed in five intermediate stations corresponds to

$$x_c = \frac{600 \times 0.8 \times 0.75}{2 \times 5} = 36 \text{ ohms per phase}$$

per station or 0.18 per unit on a kilovolt-ampere base of $5 \times kv^2$. Figure 5 is the system studied for this case. At 75 per cent line compensation, the sending-end power is 1.10 per unit kilowatt and the receiving end is 0.98 per unit kilowatt. Seventy-five per cent compensation of the line, therefore, results in practically 1.0 per unit power transfer. For a 287-kv system this is a delivered power of $0.98 \times 412{,}000 = 403{,}000$ kw.

Previous studies[5,9] have indicated that systems may be built with as much as 75 per cent compensation and satisfactory operation can be expected. Seventy-five per cent line compensation of this system requires about 0.90 reactive kilovolt-ampere of series capacitors and 0.90 reactive kilovolt ampere of shunt reactors or 370,000 reactive kilovolt-amperes of each at 287-kv. If the series capacitor and shunt reactor compensation is assumed to cost a total of $12 per one reactive kilovolt-ampere of capacitor plus one reactive kilovolt-ampere of reactor then the compensation for a 287-kv line is $370,000 × 12 or about $4,500,000. Using the previous example, the cost for transmission with five intermediate switching stations (excluding the terminal transformers and their circuit breakers) plus the compensation, is $40,800,000 plus $4,500,000 or $45,300,000. The received power limit is increased from 268,000 kw to 403,000 kw. The cost per kilowatt is accordingly reduced from $152 to $112. This figure of $112 per kilowatt can therefore be used in comparison with other methods of increasing the power limit.

Studies of this system with series capacitors were made also without shunt reactors. Interestingly enough, the power limits were very close to the same values when shunt reactors are used along the line. It appears therefore that the shunt reactor's primary function is to maintain essentially normal voltage along the line. Without the use of shunt reactors, the voltage rises to 115 per cent of normal voltage at no load near the receiving end and the same voltage rise occurs under load near the sending end, for the conditions of 1.05 sending end high-tension bus voltage and 0.95 receiving-end high-tension bus voltage, with a sending-end line section out. See Figure 6(A). Distribution of the series capacitor and the reactor compensation reduces the voltage rise along the line as is evident by Figure 6(B), which is a typical illustration of the effect of distributed compensation on the voltage gradient.

Figure 7 shows the effect of time delay in reinserting the series capacitors, measured from the time of fault clearing where the fault-clearing time was assumed to be of 0.05 second or three cycles. It is advantageous to make the reinsertion as quickly as possible. The curves of Figure 7 indicate the influence of change in generating and receiving reactance as well as the generator inertia for the case of a 600-mile line (system of Figure 5) with five intermediate stations, no shunt reactor compensation, and series line compensation of 75 per cent.

Figure 8 is a summary of a differential analyzer study which shows the variation in per unit power limit as a function of switching time and exciter time constant for a 600-mile line (system of Figure 1) with 75 per cent series capacitor compensation and without shunt reactor compensation.

When Figure 8 and Figure 2(B) are compared, a good comparison is obtained of the effect of series capacitor compensation, as all of the other system characteristics (Figure 1) were kept constant except for a change in voltage regulator stabilizer time constant (T_s). The sending-end power limit for a fault-clearing time of 0.06 second and an exciter time constant of $T_e = 0.68$ second has been increased from a P_S of 0.735 to 1.07. The latter value is practically the limit obtained under the same conditions for a 200-mile uncompensated line, Figure 2(A). In other words, the effect of 75 per cent series capacitor compensation has in effect increased the power limit of the 600-mile line to that of an uncompensated 200-mile line.

4. Intermediate Synchronous Condenser Compensation. A study of the effect of intermediate synchronous-condenser capacity was made to determine the effectiveness of this method in increasing the power limits of the 600-mile system. Previous steady-state stability studies[10] have indicated the desirability of keeping the transient reactance of the intermediate synchronous condenser as low as practicable and distributing the synchronous-condenser capacity along the line. The

Figure 6. Voltage gradient for 600-mile double-circuit line with 75 per cent series capacitor compensation. System shown in Figure 5

A. No shunt reactor compensation, with one of the sending-end 100-mile sections out; $V_S = 1.05$; $V_R = 0.95$; $P_S = 1.10$; $P_R = 0.95$
B. With distributed shunt reactor compensation; all line sections in; $V_S = 1.0$; $V_R = 1.0$; shunt reactor reactive kilovolt-amperes = series capacitor reactive kilovolt-amperes at unit load; $P_S = 1.10$; $P_R = 0.95$

Figure 7. Transient stability limits for 600-mile 75-per cent series-compensated transmission line showing effect of time delay in reinserting series capacitors (see Figure 5 for system)

No shunt reactor compensation; $V_S = 1.05$; $V_R = 0.95$; series capacitors bypassed on occurrence of fault and reinserted at time shown on abscissa after fault has been cleared; fault-clearing time is 0.05 second

Curve	x_l	x_m	H_g
1	0.30	0.15	4
2	0.30	0.25	6
3	0.30	0.25	4
4	0.30	0.25	2
5	0.40	0.25	4

present transient stability study of the 600-mile line case also showed the desirability of keeping the reactance as low as practicable, and distributing the available capacity at more than one intermediate location. The optimum distribution for the transient case is dependent, among other factors, on the location of the faulted line section. For example, if an intermediate synchronous condenser for the system of Figure 5 (without either series or shunt compensation) is placed at the midpoint, having a per unit rating of 1.25 and a transient reactance including its high-voltage transformers of 0.25 on its own rating, the sending power limit is increased from 0.71 per unit ($x_g = 0.30$) to 0.90. If the same condenser capacity is equally distributed at the five intermediate stations, the sending-end power limit is increased to 0.98. If the synchronous condensers were distributed to obtain the highest power limit for a given system, the received power limit would be still further increased to at least 1.03 for this particular amount of synchronous-condenser capacity.

The foregoing limits are based on calculations using constant voltages behind the transient reactances for all the synchronous machines. If quick response excitation systems are used, particularly at the intermediate synchronous condenser locations, the required synchronous condenser capacity may be further reduced. The use of intermediate synchronous condensers therefore requires the use of synchronous condensers of special characteristics, to be competitive with series capacitors as a means of improving the stability limits of long-distance transmission circuits. When special synchronous condensers, including quick response excitation systems, are used, they may have a rating comparable to that of series capacitors for the same power limits.

If the system has intermediate loads requiring synchronous-condenser voltage and reactive-kilovolt-ampere control at these intermediate points, then the benefits of the synchronous condenser are increased.

5. *Intermediate Shunt Reactive Control Using Static Capacitors.* Consideration has also been given to the possibilities of using intermediate controlled shunt reactive kilovolt-amperage for increasing the power limits. Dr. E. F. W. Alexanderson has proposed the use of special arrangements of reactors and capacitors to obtain voltage control whereby the correction can be applied smoothly rather than in sudden large increments.[11]

Consideration of such schemes indicates that, if the intermediate correction is distributed, higher power limits are obtained for a given total corrective capacity. Typical of the results obtained are those shown on Figure 9 with control only at the midpoint, whereby the sending-end power limit may be increased from 0.71 to 0.95 per unit, with a resultant capacitive corrective kilovolt-amperage (reactive) of 0.5 per unit which for a 287-kv system corresponds to a capacitive kilovolt-amperage (reactive) of 206,000, and an inductive kilovolt-amperage (reactive) of 412,000, if the resultant capacitive kilovolt-amperage (reactive) is to be controlled by variation of the inductive kilovolt-amperage (reactive). In the calculation, it was assumed that there were available equal amounts of lagging and leading reactive kilovolt-amperage at the midpoint and that they were applied instantaneously and smoothly so as to obtain a change in corrective current up to the limit of the capacity assumed for each case, with a regulation characteristic of 0.20 per unit for each 0.01 per unit deviation from normal voltage.

II. 600-Mile Transmission With Mid-Point Generation

The following presents some of the results of a study of 600-mile power transmission with and without mid-point generation. The systems studied are shown in Figure 10. Figure 10(A) shows the system which may be considered the initial development of a transmission system with a generating station 300 miles from its load center with three transmission lines and two intermediate switching stations. Figure 10(B) shows the same system but with another generating station located 600 miles from the load center and interconnected into the transmission system at the first generating station. From a study of the system of Figure 10(A), it is found, for the representative reactances chosen, that the power limit

Figure 8. Transient power limit for 600-mile 75-per cent series-compensated line

System conditions the same as Figure 1 except capacitors as shown dotted in Figure 1 assumed to be in circuit (75-per cent line compensation, $x_c = -0.18$ at each intermediate switching station)

Figure 9. Transient power limit for 600-mile line using controlled capacitors and reactors at the mid-point switching station

System consists of five intermediate switching stations similar to Figure 5. Corrective reactive kilovolt-amperes of 0.20 per unit applied for each 0.01 per unit of voltage variation from unit voltage at mid-point. Resultant kilovars equal to capacitive reactive kilovolt-amperes shown on abscissa. $H_p = 4.0$; $X_m = 0.25$; $V_R = V_S = 1.0$; $x_p = 0.30$; $H_m = \infty$; base kilowatts = base reactive kilovolt-amperes $= 5(kv)^2$

of the sending-end power for a 3-phase fault near the sending-end bus of a duration of four cycles is 1.33 per unit, that is, on the kilowatt base of $5 \times kv^2$, for a 287-kv system, this is 550,000 kw.

The effects of variation in the receiving-end reactance were also studied. The power limit was reduced almost 15 per cent by a 100 per cent increase of the receiving-end reactance. It is significant that the receiving-end reactance is quite important in determining the maximum power transfer and that in the design of a system for receiving large blocks of power from distant stations it is essential for good economy to keep this receiving-end equivalent reactance as low as is practical by a rational circuit arrangement. It becomes particularly effective to bus all high-voltage circuits near the receiving end directly together. Fortunately this can now be more readily accomplished with the development and increasing use of high interrupting-capacity circuit breakers.[19]

Keeping the output of the mid-station generator number *1* at 1.33 per unit, corresponding to its maximum power limit with three lines, the Figure 10(B) system was analyzed to determine the maximum total sending-end power that could be transmitted with stability. This limit was found to be 1.73 with 1.33 from generator number *1* and 0.4 from generator number *2*. This corresponds to a loading on the two circuits from the distant generating point of 160,000 kw for a 287-kv system. The total received power (P_R) for this case is $1.62 \times 5.0 \times (287)^2 = 666{,}000$ kw. As this is a relatively light loading, means were considered as to how to obtain an increase in the loading particularly from the distant station.

If the mid-station reactance was halved and the inertia was doubled, which would correspond in effect to interconnecting to a moderate amount of system capacity at this point, see Figure 10(C), the power limit for the distant generating station was increased from 0.4 per unit to 0.85 per unit. If the mid-station reactance was further reduced to one-third of its original value and its inertia trebled, the power limit for the total generating station was increased to 0.9. At this loading the critical fault moves from location number *1* at the mid-station to location number *2* at the distant generating station. With this doubling or trebling of the equivalent capacity at the mid-point, the power limits of the system approach those which may be considered reasonable from an economic standpoint. For a 287-kv system the mid-generating station remains at 550,000 kw and the output of the distant station is 370,000 kw. It is estimated that the loadings of Figure 10(C) would be realized if the tie is made to generating capacity of twice that of generator number *1* and with an autotransformer bank capacity of about 300,000 kva for a 287-kv system. The additional power delivered to the load from the 600-mile distant source of the Figure 10(C) system as compared with system 10(A) is 0.76 per unit. This was obtained by the addition of 900 circuit miles of line, approximately 22 circuit breaker positions, and a 300,000-kva autotransformer bank.

Assume again for a 287-kv system the additional power delivery is 315,000 kw. The cost of the additional transmission circuits at $30,000 per mile is $27,000,000; the 22 circuit breakers at $200,000 per position are $4,400,000; the autotransformer bank installed at $3.00 per through kilovolt-ampere installed is $900,000. This gives a total of $32,300,000. Transmission costs $32,300,000/315,000 kw = $101 per kw. This figure, although only approximately obtained, indicates that the connection to intermediate system capacity when possible compares quite favorably with the straightaway compensated transmission cases previously considered and may result in the most economic transmission system.

It may be concluded here that a system of substantial line loadings per circuit can be realized even for 600 miles if the high-tension lines are tied directly together and full use is made of generation or system capacity along the line of the order of two to four times the capacity of the distant generator source. It should be kept in mind that intermediate switching stations and a low-reactance receiving system are also quite necessary. The important conclusion is that by rational system design heavy line loadings are realizable at relatively small increase in cost, resulting in important reductions in the cost per kilowatt for transmission.

Effect of Series Capacitors and Mid-Point Generation (600-Mile Transmission)

The following present some results of the studies made to determine the influence of series capacitors used with mid-point generation, keeping the mid-point generation again at a value corresponding to the power limit of 1.33 per unit, Figure 10(A). Using series capacitors in the system of Figure 10(B) to compensate for 50 per cent of the line reactance from the mid-generating point to the distant generating point and shunt reactors to obtain essentially unity power factor at the terminals of the distant generating station, the power limit of the distant generating station was only increased to 0.5 per unit as contrasted with 0.4 per unit with no compensation.

Using the Figure 10(D) system which has a fifth circuit from generator number *1* to the load, with 70 per cent series capacitor compensation of the two circuits from generating station number *1* to generating station number *2*, and sufficient shunt reactors to obtain unity power factor at the terminals of generator number *2*, the power limit of the distant generator was increased to 1.0 per unit. Accordingly, by the use of 70 per cent series capacitor compensation in the lines to the distant station with an equal reactive kilovolt-amperage of shunt reactors and the addition of two 600-mile circuits, it is possible to obtain a reasonable loading of the distant station. P_R increased from 1.25 per unit for the system of Figure 10(A) to 2.10 per unit for the system of 10(D) giving an increase of received power of 0.85 per unit. For the case of Figure 10(D), again assuming a 287-kv system with the previously assumed costs, the following tabulation may be made up:

Figure 10. Transmission systems studied to determine effect of mid-point generation

Base kilowatts = base kilovolt-amperes = $5(kv)^2$

A. Initial system development. Power limit: $P_{G1} = 1.33$; $P_R = 1.25$

B. Initial system development plus extension of system for transmission of power from 600 mile distant source. Power limit: $P_{G1} = 1.33$; $P_{G2} = 0.40$; $P_S = P_{G1} + P_{G2} = 1.73$; $P_R = 1.62$. Critical fault: location number 1

C. System B with intermediate system interconnection assumed equivalent to halving x_{g1} and doubling H_{g1}. Power limit: $P_{G1} = 1.33$; $P_{G2} = 0.85$; $P_S = P_{G1} + P_{G2} = 2.18$; $P_R = 2.01$

D. System using series capacitors and additional 300-mile circuit added to that used by system of B. Power limit: $P_{G1} = 1.33$; $P_{G2} = 1.00$; $P_S = P_{G1} + P_{G2} = 2.33$; $P_R = 2.10$

Line:

$x = 0.8$ ohm per mile

$r = 0.08$ ohm per mile

$y = 5.2$ micromhos per mile

Receiving End System:

$$X_M = \frac{0.50}{\text{number of receiving end circuits}}$$

$H_m = \infty$

Generators (Generator kva rating assumed equal to kilowatt output at stability limit):

$x_{g1} = 0.30$ on kilovolt-ampere rating

$x_{g2} = 0.30$ on kilovolt-ampere rating

$H_{g1} = 5.0$ on kilovolt-ampere rating, seconds

$H_{g2} = 5.0$ on kilovolt-ampere rating, seconds

Fault:

Three-phase, 0.067 second or four cycles

1,200 circuit miles at $30,000 per mile = $36,000,000

28 circuit breakers at $200,000 per position = 5,600,000

175,000 reactive kilovolt-amperes of capacitors and 175,000 reactive kilovolt-amperes of shunt reactors at $12 per reactive kilovolt-ampere = 2,100,000

Total cost = $43,700,000

Increase in received power realized by above investment = $0.85 \times 5(287)^2 = 350{,}000$ kw

Transmission cost per kilowatt from 600 mile source = $\frac{\$43{,}700{,}000}{350{,}000 \text{ kw}} = \$125.$

This cost per kilowatt corresponds sufficiently close in relation to the previous costs per kilowatt to warrant the conclusion that there may be several system designs achieving heavy line loadings which may need consideration for any given case. These studies confirm the conclusion that the use of series capacitors with shunt reactors may be used as a benchmark for estimating long-distance transmission line costs. More detailed and complete studies of any given system will reveal possible further improvements which may result in substantial savings.

Discussion

J. G. Holm (New York, N.Y.): In his very interesting paper Mr. Crary gives an up-to-date presentation of the long-distance power transmission problem. Mr. Crary gives his data specifically for single conductors but mentions that these data may be used also in the study of dual-conductor lines. Since there has been lately an increased interest in bundle-conductor lines, as indicated by five papers presented on this subject at the 1950 International Conference on Large High-Voltage Electric Systems meeting in Paris and by actual application of bundle conductors on 220- and 380-kv lines now being erected in Sweden, it may perhaps be of interest to discuss briefly the bundle-conductor lines.

To find out where we stand in this subject, I made a study of bundle-conductor lines comparing single-circuit single-, dual- and triple-conductor lines transmitting power at 345 kv over distances of 100, 300, and 500 miles.

In each case four conductors were taken: two copper conductors of the *HH*-type of two different cross-sections, and two ACSR (aluminum cable steel reinforced) expanded conductors of cross-sections of the same equivalent copper as the corresponding copper conductors. The diameters of dual and triple conductors were so chosen that the total fair-weather corona loss per mile, determined for a certain altitude and temperature, was the same in the single-, dual- and triple-conductor lines. Disruptive critical voltages and gradients were calculated,

and then conductor diameters determined from data given by Temoshok.[1] The dual conductors were horizontally spaced at a 15-inch separation, and the triple conductors were located at the corners of an inverted equilateral triangle with 15-inch sides. Thus while the copper conductors for single-conductor lines were 1.5 inches in diameter, and the ACSR's had a diameter of 1.75 inches, the diameters of dual conductors were about 68 per cent and those of the triple conductors, about 53 per cent of the diameters of corresponding single conductors. The total copper, or equivalent copper, cross-section of the bundle conductors was taken equal to the copper cross-section in corresponding single-conductor lines.

For conductors thus selected the electrical design of lines was made, and their kilowatt rating established. The bundle conductors have a smaller reactance and greater line capacitance than single conductors. In order that this characteristic can be made use of to full advantage, a correspondingly greater generating capacity was assumed at the sending end. The lines were provided with receiving-end synchronous condensers for full-load to no-load operation, with the condensers supplemented by receiving-end reactors where this was economical for the absorption of the excess lagging kilovolt-amperes. The lines have no series-capacitor compensation. System power limits were determined, and the line ratings were established sufficiently below the power limits to give assurance of stability in the steady state. Thus the ratings of all dual-conductor lines were uniformly about 21 per cent and those of the triple-conductor lines, about 37 per cent above the ratings of corresponding single-conductor lines. Total system losses were calculated in both the line and the terminal equipment. In order to reduce the no-load losses and the mid-point no-load voltages in the 500-mile lines, all these lines were equipped with mid-point reactors.

In all systems conductors were supported by steel structures of the rotating type. All mechanical calculations were made for heavy-loading conditions, with simultaneous ice and wind loads taken on all conductors.

All systems were suitably protected by ground wires, counterpoises, and so forth. The pull on insulators in the bundle-conductor lines was calculated, and mechanically stronger units, as well as additional parallel insulator strings, were placed on those lines where this was required. On the dual- and triple-conductor lines with the ACSR conductors, armor rods were placed on each conductor. Spacers were placed on all bundle-conductor lines according to practice adopted in Swedish lines.[2]

System capital and annual costs were calculated for the entire system, comprising the line, terminal substations and the mid-point reactor substation (in the 500-mile lines). The cost of the right-of-way was omitted. Costs were those prevailing during the first quarter of 1949. Estimates were made of the specific hardware required by the bundle conductors. The line erection costs for the dual-conductor lines were taken at a higher figure than for single-conductor lines, and at still higher figure for the triple-conductor lines. The expenses for maintenance and operation of the bundle-conductor lines were taken at figures higher than those for single-conductor lines. The cost of all system losses, including those at no-load, was included.

Table I

Conductors	Line Length, Miles	Average Per Cent Lower Cost Per Kw	Maximum Per Cent Lower Cost Per Kw (in one case)
Dual	100	4.4	9.0
	300	5.3	8.8
	500	5.7	8.3
Triple	100	9.8	14.8
	300	10.1	14.8
	500	10.9	14.1

Table II

Conductors	Line Length, Miles	Cost of Generating Capacity A $/Kw: Average Per Cent Lower Cost Per Kilowatt-hour	Cost of Generating Capacity A $/Kw: Maximum Per Cent Lower Cost (in one case) Per Kilowatt-hour	Cost of Generating Capacity 35.3 A $/Kw: Average Per Cent Lower Cost Per Kilowatt-hour	Cost of Generating Capacity 35.3 A $/Kw: Maximum Per Cent Lower Cost (in one case) Per Kilowatt-hour
Dual	100	3.5	8.0	2.4	6.2
	300	3.3	6.3	1.7	4.1
	500	3.0	6.2	1.4	4.0
Triple	100	7.9	12.5	6.0	10.0
	300	7.1	9.7	3.8	6.3
	500	6.0	10.1	2.3	5.8

For the four cases, the average capital cost per mile of the transmission line alone for the dual-conductor lines was 12.2 per cent greater than the average cost of single-conductor lines, with a maximum of 15.1 per cent in one case. In the case of triple-conductor lines, the average increase was 21.4 per cent, with a maximum increase of 28.3 per cent in one case. The Swedish calculations, reported in 1950,[3] for one case of a 380-kv dual-conductor line show an increase of 19.8 per cent, compared with a single-conductor line, per kilometer.

For the loadings used, capital costs of the entire system, per kilowatt transmitted, for the dual- and triple-conductor lines were lower than for single-conductor lines, for all the three distances investigated. The decrease in costs for the four cases studied are given in Table I of this discussion.

The annual costs of the entire system, per kilowatt-hour, for the dual- and triple-conductor lines were also lower than for single-conductor lines, for all three distances. The average percentage decrease in costs for the four cases studied, for two different costs of generating capacity are given in Table II of this discussion.

The Swedish calculations,* reported in 1948,[4] for one case of a dual-conductor 380-kv line show capital costs for the entire system, per kilowatt, 8.5 per cent smaller than for the 380-kv single-conductor system. They also show annual costs for the entire system to be 3.3 per cent less than for the single-conductor system. In these calculations losses are included.

* It is not clear if calculations were made for a 280-mile line, or for a line of twice this length.

The costs given in this discussion are in good agreement with the Swedish costs so far referred to. However, the Swedish engineers,[3] in discussing the annual costs of an entire 380-kv dual-conductor system ("with stability", as they say), state that the costs on this system for a 300-mile line are 9.2 per cent less and for a 600-mile line, 11.9 per cent less than the annual cost of a 380-kv single-conductor system of corresponding length. These are very high figures. In my total of 48 cases they have been approached, or exceeded, only four times. Moreover, it is indicated in their paper that the annual economy of a dual-conductor system increases as the length of the line increases, varying from 5.1 per cent on a 125-mile system to 11.9 per cent on a 600-mile system. Even though this dual-conductor Swedish line has 30 per cent more equivalent copper than the single-conductor line, calculations made on the basis of their assigned ratings place in doubt the indication that relative economy increases with the length of the line. It is possible that the figures they reported in 1950 may be affected by the fact that their system is State-owned, so that the cost of hydro-generation is very small, and taxes none. Their annual charges are a little more than half the annual charges applied by private public utilities in this country.

In general, while the data here reported show that under some conditions there are significant economies for bundle conductors, the comparison may be reversed for other conditions. If the amount of power to be transmitted is fully within the capacity of a single-conductor line having a sufficient amount of copper, or equivalent copper, then it is possible that it will be more economical than the inherently higher capacity and more expensive dual- or triple-conductor line. Many variables, such as for example the general national price level or possible differences in the engineering approach, may produce some changes in the relation between single- and bundle-conductor costs and cause appreciable deviations from the average percentage values. Therefore, it is my opinion that the question of whether, and to what an extent, the bundle-conductor lines are more economical must be decided on the merits of each particular case.

Whatever the economic features of bundle conductors may be, their technological advantages and disadvantages must be given full consideration. No attempt will be made at this place to discuss this phase of the subject.

W. A. Morgan (United States Bureau of Reclamation, Denver, Colo.): I want to

congratulate the author on his worthwhile and timely analysis of factors affecting the design of a long-distance power transmission system. The general problem Mr. Crary has assumed is a practical one, and the analytical treatment he has given it establishes several fundamental ideas to be considered in any system of this type.

The Bureau of Reclamation is currently making studies of the proposed power system which will be required when power developments above Hoover Power Plant are built. If all the power potentialities within 300 miles upstream from Hoover Power Plant are utilized, this new power would amount to 2,500,000 kw to 3,000,000 kw capacity in three or four power plants. The purpose of these studies is to establish nominal voltage and arrangement of transmission lines for the ultimate development, and then to determine the program for development of this system as each power plant is to be built so that the initial system will fit into the pattern of a well-designed ultimate system.

It is brought out by the author that series capacitors may be used as a basis for evaluating quite accurately the expected cost of the long-distance transmission. Also, the 75 per cent compensation in capacitors is assumed to be lumped at the intermediate switching stations. Have the technical difficulties of relaying for line faults with such an installation been overcome as yet?

It is understood that in the Swedish application the series capacitors are located in the middle of a line section, and the value of compensation is less than 30 per cent, thereby assuring correct directional relaying with the presently available distance-type line relays. Would the author care to comment on the conservative approach of the Swedish engineers in regard to the application of series capacitors?

Are there any other design problems in connection with a high-voltage series capacitor installation, such as arc-gap bypass switch protection, that will require further developmental work before the manufacturers will be willing to guarantee satisfactory performance of a series capacitor installation?

It is noted that the power limit of a transmission line may be increased approximately 25 per cent if dual conductors are used. It would appear that there might be justification for dual conductors on 287-kv lines, particularly for single circuit construction, as well as on 360-kv lines as they are presently being applied. Are cost data and analysis available to demonstrate whether dual conductors are justified for 287-kv lines, either for single- or double-circuit construction?

There are two comments that are believed to be pertinent with regard to Figures 3 and 5 and the discussion of the value of intermediate switching stations. One is that it may not be practical to extrapolate the conclusion to include the case where as many as 12 transmission lines may be required. The other is that cost comparisons on an initial cost basis only may not give the full picture and that it may be more accurate to consider the total annual costs which would include operation and maintenance, amortization of investment over a period of years, and annuity for replacement.

With regard to the first point, there definitely is no disagreement regarding the value of intermediate switching stations where only two transmission lines are concerned. In this case, without the intermediate switching stations, the impedance is doubled when one line is tripped out of service; whereas with five intermediate switching stations, the impedance is increased only 17 per cent for loss of a line section.

Table III

	Transmission Line	Substation Equipment
Amortization*	0.03887 (3 per cent, 50 years)	0.03887 (3 per cent, 50 years)
Annuity†	0.01027 (100 per cent replaceable, 45 years)	0.01529 (90 per cent replaceable, 28 years)
Operation and maintenance**	0.00750	0.02750

* From *Reclamation Law*.

† *Bulletin F*, United States Treasury Department.

** From *Reclamation Manual*.

However, if there are 12 transmission lines, the benefits of intermediate switching stations is diminished. For example, if one line of the 12 is tripped, the impedance is increased about 9 per cent, without intermediate switching stations; whereas it is increased about $1^1/_2$ per cent for loss of a line section with five intermediate switching stations.

With two lines the intermediate switching stations are beneficial in reducing this change in impedance from 100 per cent to 17 per cent, which is a substantial improvement. However, considering the many assumptions that must be made in a study of a system of this size, it may be more difficult to justify reducing the change in impedance from 9 per cent to $1^1/_2$ per cent by intermediate switching stations in the case of 12 lines.

With regard to the second point, it is necessary to consider the total costs in comparing any two schemes and they may be put on an annual basis considering amortization of initial investment, annuity for replacement reserve, and operation and maintenance. The significant point here is that the factor for operation and maintenance of substations is over three times that for transmission lines, and the replacement annuity is only one and a half times that for a transmission line.

To illustrate the point, let us assume that 2,500,000 kva could be transmitted with equivalent stability 300 miles with either 13 287-kv transmission lines without two intermediate switching stations, or 12 transmission lines with two intermediate switching stations. Considering the large number of circuit breakers and the higher operation and maintenance cost factor, it would be less costly to use the system with 13 lines and no intermediate switching stations than with 12 lines and two intermediate switching stations. This is arrived at using the factors, shown in Table III of this discussion, which are to be multiplied by the initial cost to obtain the annual costs.

This method of comparing schemes on a total annual cost instead of only the initial costs is proposed.

The cost of a long distance power transmission system is so great that advantage should be taken of every means that will improve system performance and thereby reduce this cost, such as the full interconnection with generation at intermediate points and the reduction of reactance at the receiving end terminal which Mr. Crary points out. Some preliminary work we have done indicates that the reduction of receiving terminal reactance and interconnection with intermediate generation may amount to a savings of millions of dollars in over-all system costs.

In conclusion, it is desired to emphasize that papers such as Mr. Crary's are very important in bringing forth discussion and outlining the principles to follow in designing a long-distance power transmission system.

C. H. Prior (Department of Water and Power, The City of Los Angeles, Calif.): Mr. Crary's paper is of considerable interest to those of us in Southern California where large blocks of power must be transmitted over long distances. For this reason, the author's studies on the stability limits of the 600-mile system with mid-point generation and with series capacitors were of great interest, and they stimulated the desire to determine the power limits of the systems shown in Figures 1 and 2 of this discussion.

When transient stability analyses were made of the system shown in Figure 1 of this discussion, using the Department's network analyzer, it was found that with no compensation of the two 287-kv lines from the sending end to the mid-point, with 75 per cent compensation of the three 287-kv lines from the mid-point to the receiving end, and with 540,000-kw generation at the mid-point, the maximum delivered power was about 775,000 kw, with a net delivery of about 265,000 kw from the 600-mile source.

Using the author's cost-estimating data, the transmission cost for this 265,000 kw is as follows:

600 circuit miles at $30,000 per mile	$18,000,000
12 circuit breakers at $200,000 per position	2,400,000
561,000 kvar of capacitors and 561,000 kvar of shunt reactors at $12 per kvar	6,732,000
	$27,132,000
Transmission cost per kilowatt from 600-mile source	$ 102

In order to increase further the power limits of the system, 75 per cent series capacitor compensation was used in the two lines from the sending end to the mid-point

Figure 1. 600-mile 287-kv transmission system with mid-point generation and with 75-per cent series compensation between the mid-point and the receiving end

as shown in Figure 2 of this discussion. For this case the maximum delivered power was 996,000 kw, with a net delivery of 484,000 kw from the 600-mile source.

The cost for this 484,000 kw is as follows:

600 circuit miles at $30,000 per mile	$18,000,00
12 circuit breakers at $200,000 per position	2,400,000
1,470,000 kvar of capacitors and 1,470,000 kvar of shunt reactors at $12 per kvar	17,640,000
	$38,040,000
Transmission cost per kilowatt from 600-mile source	$ 79

These studies indicate the heavy line loading that can be obtained by using series capacitor compensation; however, further studies are required to determine if such heavy loading is desirable.

W. F. W. Alexanderson, and **D. C. Prince** (General Electric Company, Schenectady, N. Y.) and **C. H. Willis** (Princeton University, Princeton, N. J.): Mr. Crary has kindly included mention of our work using shunt saturable reactors and capacitors to give a continuous voltage control. There are some differences in operation between shunt and series capacitor control which should be noted. When series capacitors neutralize line reactance, the line angle is reduced. Large changes of load occur for small angular displacements between the two ends of the line. Also, of course, large voltages appear across the capacitors under fault conditions, unless protective devices are used.

With shunt compensation, on the other hand, the line angle is increased and large phase displacements accompany changes in load. It is interesting to examine the application of shunt compensation, instead of the series capacitors, to Mr. Crary's case of a 600-mile line with five intermediate switching stations. Using the same kilovolt-amperes of capacitors and twice the reactive kilovolt-amperes employed by Mr. Crary, in the section on Series Capacitor Compensation, gives approximately 0.9 for the per-unit power. (This value is obtained by extrapolating the sending-end-power of Figure 9 of Mr. Crary's paper.) This corresponds to a cost per kilowatt of power transmitted of $128.00 as compared to $112.00 for the same capacitive kilovolt-amperes used in series compensation. In computing the line cost, an appropriate addition has been made on account of the added shunt reactor.

It should be noted that the above-mentioned curve assumes the shunt kilovolt-amperes applied at the center of the line. When the shunt kilovolt-amperes used for compensation are applied at several points, as was the case for the series compensation, the comparison becomes more favorable to the shunt compensation as is stated in the paper. Since curves are not given which show the per-unit load for this line with shunt compensation applied at 100-mile intervals, no exact comparison of the relative cost of the two schemes is apparent; but the discrepancy will be somewhat less than shown in the comparison given above.

Series and shunt compensation may be compared analytically by considering the effect of the compensation on the surge impedance and line angle which will be considered loss-less to simplify the discussion. The analytical expressions for the surge impedance and angle of a Pi section are well known.

Figure 2. 600-mile 287-kv transmission system with mid-point generation and with 75-per cent series compensation of the entire line

When series compensation is used, the series impedance is reduced to a fixed lower value by the series capacitive reactance added. This reduces the surge impedance and the line angle. The maximum power transfer is increased because the surge impedance is reduced and the phase difference between the ends of the line is also reduced because the line angle is reduced.

When shunt compensation is used, the shunt impedance is increased if the compensation is inductive; but, if the compensation is capacitive, it is reduced. This permits a wide range of variation of the surge impedance and, since the compensation varies automatically to maintain a constant line voltage, the line operates at surge impedance loading over a wide range of load. The load limit is increased as in the series capacitor case, because the surge impedance is reduced by capacitive shunt compensation. This method of describing the operations may, of course, be applied to any operating scheme which maintains the same voltage at the two ends of the line under transient conditions.

S. B. Crary: The discussors have made very worthwhile contributions to the subject, some of which require no comment.

Mr. Holm has made a rather thorough study of the economics of dual-conductor lines versus single-conductor lines and, as he points out, the economic justification for dual versus single conductor lines is relatively small and may be dependent upon the particular local conditions. Mr. Holm may have avoided some of the complications of his analysis if he had assumed that the dual-conductor circuit had a resistance per mile proportional to its surge impedance, that is, $R_d = (Z_d/Z_s)R_s$ where R is resistance per mile and Z is the surge impedance. The subscript s indicates a single conductor per phase and d a dual conductor per phase. If this assumption is made it follows rather directly that the dual-conductor line can be justified (keeping all other factors equal) when the cost per mile does not exceed the ratio of the surge impedances of the two lines being compared; $C_d < C_s\ (Z_s/Z_d)$, where C is the cost per mile of the transmission line. This particular relationship is discussed in reference 1 of this discussion.

The above relationship applies when considering single-circuit lines at a single-voltage level. If the additional considerations of twin-circuit and single-circuit tower lines, including the variation in circuit voltages, the reliability, cost of right-of-way, and so forth are included then the comparison can no longer be as simple as indicated by the preceding relationship.

Apparently Mr. Holm has restricted himself, in this discussion at least, to a relatively simple comparison and it would have been helpful if he had given the line costs for the dual and single conductor lines as this appears to be the most important factor in determining the relative economy for the simple type of comparison which he has attempted to make.

Mr. Morgan has raised some very pertinent questions. We wish to assure Mr. Morgan that the relaying of the line faults will be solved as an essential requirement for the use of series capacitors, particularly when large values of compensation are used.

Mr. Morgan asks in regard to the conservative approach of the Swedish engineers in regard to the application of series capacitors. It appears from a recent paper[4] that the Swedish engineers have applied series capacitors primarily for load balancing of the 230-kv lines to decrease the real and reactive losses of the system and thereby increase the transmission capacity of lines already built. They also have indicated that this step is preliminary to possible application to the 380-kv lines. It must be kept in mind that the European transmission system design philosophy differs from that in this country in that the hydroelectric generators with their associated transmission circuit are not designed for firm power transfer, as an outage on the high-voltage line may result in loss of generating capacity. Therefore the application of series capacitors to European systems may be expected to differ in some respects from the requirements of the equipment developed for use in this country. Mr. Morgan also has asked in regard to the development of an arc-gap by-pass switch protection. We are pleased to state that such equipment has been under development and the manufacturers are in a position to quote on such equipment to meet rational system requirements.

Mr. Morgan is correct that the results shown in Figures 3 and 5 do not apply to the case of 12 parallel transmission circuits as these were made for the case of two parallel circuits. In the case of additional parallel circuits, the number of switching stations which can be economically justified would decrease for a given distance. Mr. Morgan's point is well made, that in order to make a more complete economic picture, it will be necessary to determine the cost per kilowatt-hour for transmission (mills per kilowatt-hour) rather than the investment cost (dollars per kilowatt). In the paper the investment costs per kilowatt were taken as a simple measure or indication of the relative economy of the various systems of transmission. This comparison seemed justified inasmuch as the stable loadings did not exceed appreciably the surge impedance loading of any one circuit. As other studies have indicated, it is economic to at least load the circuit up to this point. However, if the loadings of the lines are to exceed appreciably the surge impedance loadings, then it becomes necessary to make an evaluation in terms of cost per kilowatt-hour in order to determine the most economic loading and system transmission.

This comment particularly applies to Mr.

Prior's discussion as he had considered loadings of 1.25 and 1.61 times the surge impedance loading of the circuits. Undoubtedly for the assumed costs some increase above the surge impedance loading is justified. Further study would be required to determine to what extent these circuits can be economically loaded. Such a study would involve, among other things, a determination of the most economic conductor size. Mr. Prior's point is certainly a good one in that the loadings given on Figure 10 of the paper for the four systems shown may actually be increased by even greater amounts of compensation. This would require an economic study in more detail than that attempted in this paper, but may, as Mr. Prior indicates, result in an even more economic system. This would require more complete economic consideration than was attempted in the paper or in Mr. Prior's discussion.

The discussion by Messrs. Alexanderson, Prince, and Willis points out the desirability of considering the shunt compensation method. As has been emphasized, some form of compensation is fully justified, particularly for long straightaway transmission. The problem in any case, because of the large investments involved, is to determine the most economic as well as the most reliable method. In order to make such comparisons rather complete information needs to be available as to the relative costs, operating characteristics, and efficiency of the different types of equipment. One of the most encouraging features is that the transmission engineer now has available many different methods by which it is possible to overcome the stability limitations of long-distance transmission.

The Bridge River Hydroelectric Development

T. INGLEDOW
MEMBER AIEE

J. H. STEEDE
MEMBER AIEE

THE Bridge River development is a relatively high-head hydroelectric project on the eastern side of the coastal range in the Fraser River drainage area in the southern part of British Columbia. It is being constructed by the British Columbia Electric Railway Company to serve the greater Vancouver and lower Fraser Valley area. The project lends itself to economical development in progressive stages to an ultimate capacity approaching 750,000 hp. Three 62,000-hp units are now in operation. Ultimate capacity of the main project will be ten such units in a power house on the shore of Seton Lake. There are a number of novel features about this development which make it of particular interest at this time.

Location and Geographical Features

The Bridge River rises almost due north of Vancouver, approximately 110 miles distant, and flows in a generally easterly direction from near the height of land of the Cascade mountains to join the Fraser River five miles above the town of Lillooet, and 200 miles from the mouth of the latter river. In its upper reaches it is a turbulent mountain stream. At a lower stage after juncture with several tributaries, it flows through two flat basins between towering mountain ranges, then plunges downward over 1,400 feet in the last 15 miles of its course to join the Fraser.

Just above this last precipitous section the river bends southward and approaches within less than three miles of Seton Lake at an elevation almost 1,200 feet above the lake. Such is the natural setting for this high-head diversion project.

Watershed and Stream Flow Conditions

The watershed area is estimated to be 1,350 square miles, the greater part of it more than 3,000-feet elevation above sea level, and extending to mountain peaks of 7,000 to 9,000 feet. Precipitation varies over a considerable range from 18 inches or less in the valleys to considerably more at the higher elevations where it is mostly in the form of snow. As the water supply is mainly derived from those higher elevations, run-off is at a maximum in the late spring and early summer, continuing at a high level until early autumn. Low run-off occurs during January, February, and March, when temperatures even in the valleys may normally reach 10 to 20 degrees below zero. The stream flow, therefore, varies over a very wide range, the ratio of maximum to minimum daily flow recorded being of the order of 160-to-1, indicating the necessity for extensive storage facilities to take advantage of the average yield of the watershed, which is of the order of 3,400 cubic feet per second. Stream flow records compiled from measurements taken under the supervision of the Dominion Government Water & Power Bureau are available back to 1913.

Early History

The power possibilities of the site were first realized in 1912 by Captain Geoffrey Downton, a land surveyor, who discovered the difference in elevation between the river and Seton Lake, and their close proximity to each other. Subsequently, surveys and investigations were carried out sufficient to establish the power capabilities of the site, and the Bridge River Power Company was formed for the purpose of developing it. Due to a lack of market for the power, however, little or no action was taken until 1925. At that time an option was taken on the rights and properties of the Bridge River Power Company by the British Columbia Electric Railway Company, which then was giving extensive study to various projects to meet the future long-term power requirements of the Vancouver area. After a thorough investigation of the whole project, the property and assets of the Bridge River Power Company were purchased in 1926. Rate of system load growth at that time appeared to justify proceeding with construction and accordingly in 1927 preparatory work was started in connection with the driving of the first diversion tunnel.

To parallel the development of Bridge River at various stages, development of an additional plant on the Stave River relatively close to Vancouver was planned, such a plant to be utilized largely for peaking purposes when operated in conjunction with the Bridge River plant, as in its early stages particularly, Bridge River is capable of relatively high load factor operation. The first Ruskin unit as part of this Stave development was brought into service in the late autumn of 1930.

With the general depression in business which began to have its effect about that time, load growth was greatly reduced and later ceased altogether. In view of this falling off in load when the diversion tunnel was completed in December 1931, work on the Bridge River development was suspended. Prior to the outbreak of war in 1939, load conditions had not justified resumption, system capacity in the interim being obtained by further development at Ruskin. Lack of

Paper 50-136, recommended by the AIEE Power Generation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 13, 1950; made available for printing April 10, 1950.

T. INGLEDOW and J. H. STEEDE are both with the British Columbia Electric Railway Company, Ltd., Vancouver, B. C., Canada.

Figure 1. Bridge River Valley, looking eastward toward the diversion dam

materials and manpower precluded Bridge River construction during the war years, but early in 1945 detailed engineering was put in hand. There resulted considerable modification of the original design to take advantage of recent engineering developments and to more nearly meet the changing needs of the system. The overall scheme of development was not changed materially, however. Actual construction on the site was resumed in June 1946, the first unit being brought into operation eight months ahead of initial schedule on October 23, 1948. The second followed on May 6, and the third on December 14, 1949.

Component Parts of the Project

The component parts of the project at its present stage are as follows: a diversion dam in the Bridge River Valley to create a regulating pond and maintain a head of water over the tunnel intake; a 13,200-foot tunnel through Mission Mountain to divert the water from the Bridge River Valley to the mountainside above Seton Lake; steel penstocks some 2,100 feet in length down the side of Mission Mountain and crossing under the main line of the Pacific Great Eastern Railway; a building housing three vertical impulse turbines with generators and associated hydraulic and electric controls and servicing facilities, this building being designed for extension to accommodate seven additional units at a later date; a switching structure on several levels on the rapidly rising ground at the rear of the powerhouse; a 130-mile 230-kv steel tower transmission line terminating at Horne-Payne Substation in Vancouver; a rock-fill storage dam some 35 miles up the Bridge River Valley from the tunnel intake which will ultimately provide 570,000 acre-feet of storage. Reference will be made later to the additional features which will form part of the ultimate development; a second storage dam in the vicinity of the tunnel intake and a second tunnel through Mission Mountain parallel but on the east side of the present one.

Relative locations of all the present facilities are shown in Figure 2, both in relation to one another and to Vancouver. The various parts of the development now are described in some detail.

Figure 2. Map showing Bridge River Development in relation to Vancouver

The Diversion Dam

This is an earth- and rock-fill dam with an impervious clay core, just over 60 feet high at the center of the old stream bed

Figure 3. Diversion dam, sectional views

and having a crest length of 820 feet. An unusual feature is its width as compared with the crest length, it being over 600 feet from toe to heel as indicated in Figure 3, which shows a cross-sectional view. This width was necessary owing to the foundation conditions. While the walls of the valley, which assume canyon-like proportions at this point, are of solid granite, no bedrock foundation was found in the narrow channel although test boring was carried out to a considerable depth, both at the dam location and for two or three miles downstream. Materials underlying the dam consists of a deposit of silt, sand, gravel, and boulders varying in depth up to 50 feet overlying a bed of blue clay 30 to 35 feet thick. Owing to the nature of this underlying clay, it was essential that consolidation due to the superimposed weight of the dam take place very gradually and, accordingly, the side slopes had to be made unusually flat to avoid abrupt changes in loading.

Figure 4 (left). Plan of diversion dam

Figure 5 (below). Profile of tunnel

As shown in Figures 3 and 4 a concrete-lined spillway channel is provided to carry flood water downstream. This channel excavated through the solid rock of the south abutment is 50 feet wide and 900 feet long. Discharge is controlled by two sluice gates 25 feet wide by 40 feet high, and the dam is protected from overtopping by a concrete overflow spillway weir 250 feet wide, 15 feet lower than the crest of the dam. The excavation of the spillway provided 209,000 cubic yards of rock, all of which went into the dam and comprised about two-thirds of the total rock fill used, the remainder being obtained from nearby rock slides. Talus fill amounting to nearly 70,000 cubic yards was trucked one mile. It was necessary, however, to go 29 miles up the valley to find material for the clay core amounting to 26,000 cubic yards.

Work on the dam site commenced on June 4, 1946. Construction of the diversion channel continued without interruption throughout the winter of 1946, it being essential that it be completed to permit the river to be diverted through it before the 1947 spring freshet, in order that work could proceed on the body of the dam. Diversion of the river took place on April 28. On June 13, 1947, driving of sheet-steel piling for the cut-off trench on the dam center line was commenced and was followed by the placing of the first clay for the core, coffer dams having been previously completed on the upstream and downstream sides of the dam area. The clay core was completed on August 18, 1948, and the sluice gates were closed for the first time on November 10, 1948.

Care was used during construction to determine that the underlying clay strata was not stressed unduly. Piezometers were established in the upstream coffer dam before the commencement of rock fill, and in addition a number of settlement plates were established at the bottom of the fill downstream on the dam center line, and also downstream from the dam center line. Frequent readings were taken during the progress of construction, and upon completion of the dam further piezometers were established on the

dam center line and downstream from the dam center line as the original piezometers in the upstream coffer dam were under water. Subsequently, additional monuments were established on the dam center to permit periodic readings to be taken to determine the extent of settlement.

This dam with spillway elevation of 2,000 feet backs up the water for $7^1/_2$ miles, impounding approximately 18,000 acre-feet, roughly half of which is available for regulating purposes and provides a head of water on the tunnel intake.

Tunnel, Tunnel Intake and Outlets

The tunnel intake is in the form of a massive tower structure two miles above the diversion dam, provided with two entrance bays with water passages through the base and leading up into the interior of the tower, and thence into the tunnel. The control gate is of balanced cylindrical type, 20 feet in diameter with open bottom, and sits in an upright position on an annular ring encircling the water opening in the base of the tower. In its closed position the water from the regulating pond rises to its level inside the cylinder but, being contained within the cylinder, is prevented from flowing into the tunnel. Screen racks are fitted and outside the screens a heavy grillage of concrete columns and beams extending up to high-water level protects the screens from coarse debris or floating ice. To provide for the possibility that the future lower storage dam will be downstream from this intake, the base is designed to be capable of extension to a height of 217 feet. All features of the intake and cylindrical gate have been designed to meet the pressures which would result from an ultimate reservoir level at an elevation of 2,140 feet.

The tunnel is 13,200 feet in length, fully lined with a gradient of 0.73 foot per 100. The first 640 feet is of circular section 14 feet 3 inches in diameter. The next 10,560 feet is of horseshoe shape but of equivalent cross-sectional area. At the 11,200-foot point the tunnel breaks down into two branches, one of 8 feet 10 inches and the other of 10 feet 10 inches equivalent diameter. These also are fully lined. The smaller one, completed when the main tunnel was driven almost 20 years ago, serves Number 1 and Number 2 units; the larger branch was just completed in 1949 and will serve units Number 4 and 5 as well as the present Number 3.

In the initial branch a surge chamber was formed by enlarging the cross-sectional area of the tunnel for a distance of 185 feet and by driving a vertical shaft 300 feet long with a lined diameter of 7 feet to the ground surface. The design of this surge chamber was based on the use of smaller units than those now utilized, which may necessitate enlarging the vertical shaft at some later date. Operating experience up to this time has not indicated that there is any serious limitation.

The recent larger tunnel branch is also provided with a differential-type surge chamber in the form of a vertical shaft through rock. This vertical shaft is 20 feet 6 inches in diameter for the first 205 feet of its rise, with an inside steel pipe riser 9 feet in diameter, then reduces to 10 feet for the remaining 90 feet to the ground surface. In this case there is no enlarged section in the tunnel adjoining the vertical shaft. Instead of the branch tunnel being extended to the portal at full diameter, however, necessitating a manifold or a complicated pipe structure to serve three pressure pipes, the branch tunnel breaks down to three 6 foot 3 inch tunnels at the base of the surge shaft. This arrangement, as well as a plan of the smaller 8 foot 10 inch tunnel, is shown in Figure 6.

In driving the original tunnel 20 years ago, considerable difficulty was encountered with soft rock and water entering the tunnel bore under pressure to the extent that a 430-foot section was abandoned and a fresh start made on an offset to avoid the trouble zone. The offset section also proved troublesome but was eventually pushed through to more solid ground. The soft and crumbling nature of the rock throughout the greater part of the tunnel length necessitated the com-

plete lining which had not been contemplated. In driving the new tunnel branch in 1949, conditions proved to be worse than those encountered in the first tunnel branch and an extremely bad section persisted for a distance of approximately 300 feet. Progress of tunnelling through this section was heartbreakingly slow, taking slightly over six months or an average of less than two feet per day.

Penstocks

In the initial branch tunnel the penstock steel commences 340 feet inside the tunnel and extends to the portal where there is a Y with a butterfly valve on each of the individual pressure pipes supplying the number 1 and 2 units. The steel liner in the tunnel is 106 inches in diameter and of uniform thickness, $1^{3}/_{16}$ inches.

In the new tunnel branch, the number 4 and 5 tunnels were not lined except for a short section between the base of the surge chamber and the location of bulkheads which were installed in each of these tunnels to close them off until they are required for units number 4 and 5. Number 3 tunnel was lined to the commencement of the penstock section, which is steel pipe $73^{7}/_{8}$ inches inside diameter and 13/16 inch in thickness, and extends 80 feet inside the tunnel portal. A butterfly valve also is installed in this penstock outside the portal at the top of the pressure pipe. In each pipe there is a venturi section about 100 feet below the butterfly valve. The valve is designed to close automatically in case of a break downstream, being actuated from a differential pressure device operating on this venturi section, or it can be closed by push button from the powerhouse. The valve-operating mechanism is an oil-pressure type controlled electrically by a d-c motor.

The pressure pipes are 2,100 feet in length, $75^{1}/_{8}$ inches constant outside

Figure 13. View of switchyard from above, Seton Lake beyond

diameter varying in thickness from 7/8 inch at the top to $1^{13}/_{16}$ inches at the bottom. Joints between sections of the tunnel liner were field-welded and -tested by gamma rays, photographic film being wrapped around the outside of the pipe and a lead capsule containing radium passed along the inside. Joints between sections of the pressure pipe were made with Dresser couplings, giving an expansion joint every 40 feet on the hillside. Designed for 1,000-pound-per-square-inch pressure in shop test, a coupling remained tight at 1,500-pound pressure. We are advised by the manufacturer that this is the first time that these couplings have been applied at such pressures. Three weights of coupling are used, all utilizing formed rubber continuous ring gaskets 5/8 inch by $2^1/_4$ inches compressed under an inner steel cylindrical ring by two 3-inch by 3-inch steel followers drawn up by bolts, 60, 80, or 90 in number, depending on the weight of coupling.

Erection of the pressure pipe sections weighing up to 30 tons each on a steep mountain side, the slope of which reached 41 degrees, presented a problem which was solved by the use of a gantry running on steel rails laid on top of the penstock footings and hauled up the the hill by an electric hoist above the portal. The gentry in operation is shown in Figure 7.

Each pressure pipe terminates in a spherical valve, the purpose of which is to provide a seal at that point to permit work to be carried out on the turbine whenever this may be necessary. This is a 54-inch plug-type valve, Figure 8, which with trunnions but without operating levers weighs 37 tons. It embodies a retractable joint capable of four inches in and out movement to permit uncoupling from the penstock for removal or replacement.

Turbines

The turbines are of vertical-shaft impulse type, equipped with six nozzles and rated 62,000 hp at 1,118 feet net head and 300 rpm. The six nozzles are supplied by a single spiral casing, comprised of eight steel castings. The largest, containing the number 1 nozzle, has an inlet diameter of 66 inches and weighs nearly 12 tons after machining. Diameter of each nozzle is $10^1/_2$ inches. The runner has 20 buckets, each $26^1/_2$ inches wide and weighing 550 lbs. They are bolted to a solid steel disc 6 inches thick. Outside diameter of this runner is $117^1/_2$ inches, pitch diameter 95 inches. Power is delivered to the generator by the 24-inch diameter turbine shaft.

The turbine is controlled by a Woodward-type governor which transmits the proper impulses through a conventional servomotor arrangement to a rockshaft linkage which actuates individual jet controllers of hydraulic piston type, one to each nozzle. Jet deflectors are provided to operate automatically in the event of sudden loss of load.

These units are believed to be the largest vertical impulse turbines ever built, and except for certain parts, were manufactured in Vancouver to design of a well-known American turbine manufacturing firm.

These units represent not only a forward step in impulse turbine design in point of size, but have broken new ground in the efficiencies obtained. Gibson tests run on number 2 unit after it went into service have indicated an efficiency as high as 92 per cent at 60 per cent load and efficiencies in excess of 90 per cent from 33 to 93 per cent of rated output.

Certain bucket trouble experienced on number 1 unit after nine months' operation and on number 2 after much less time was found to be due to faulty foundry work, which was remedied by the installation of new buckets.

Generators

The generators are rated 50,000 kva, 0.9 lagging power factor, 13,800 volts, 3-phase, 60 cycle, 300 rpm, 60-degree Centigrade rise and have class-B insulation. They are of conventional design; weight of both generator and turbine being supported by a Kingsbury thrust bearing with upper and lower guide bearings. They are totally enclosed with eight water coolers mounted on the periphery of the stator absorbing the generator heat loss from the circulating air. Facilities for a water spray controlled by a manually operated valve are provided for use in the event of fire developing in the windings. The main exciter, pilot exciter, and permanent magnet generator for operating the governor mechanism are located above the upper bracket and are direct connected to the generator shaft. Due to the comparatively high speed and small number of poles for waterwheel-driven generators of this capacity, the units occupy a floor space only 20 feet square, but the over-all height is 23 feet above the stator foundations. For the same reasons the efficiency is quite high, the manufacturer's guarantees being 97.8 per cent at full load, 97.3 per cent at three-fourths load and 96.4 per cent at one half load, all at 0.9 power factor lagging.

Stability studies simulating conditions on the system as a whole indicated that while the rest of the system was stable, being relatively closely coupled electrically, there was a tendency for Bridge River to swing out of synchronism during system faults, and for this reason a higher than normal short-circuit ratio was speci-

Figure 14. Elevation through switchyard

fied. Under initial conditions also, with only one transmission line, a greater spread in operating voltage was required, it being specified that each machine should operate satisfactorily over a range from 14.5 down to 11 kv. Prior to the installation of a synchronous condenser at the receiving station, this range of generator voltage was covered under normal operating conditions.

Design characteristics of the generators are as follows:

Synchronous reactance:	$X_d = 100$ per cent
Transient reactance:	$X_d' = 30$ per cent
	$X_q' = 53$ per cent
Subtransient reactance:	$X_d'' = 25.6$ per cent
	$X_q'' = 25$ per cent
Negative sequence reactance:	$X_2 = 25.3$ per cent
Short-circuit ratio = 1.18	
Calculated flywheel effect (WR^2) = 7,625,000 pounds times square feet	

The stator windings are Y-connected with the neutral fully insulated from ground. For ground detection in the windings, three special potential transformers arranged with grounded-Y primary, open-corner-delta secondary are connected to the line leads. The stator winding is in two parallels with six line and six neutral leads brought outside the machine, permitting the use of double primary current transformers with primaries in opposition for split-phase protection. Additional current transformers on the phase and neutral terminals are utilized for differential protection.

Indication and record of winding temperatures are obtained from 10-ohm resistors imbedded between coils in the stator slots.

The 24 pole rotors are conventional in design, with the pole pieces dovetailed into slots in a laminated rim which in turn is shrunk on a cast steel spider, the whole being designed for twice normal speed. Rotor diameter is 155¼ inches. Bearings are water cooled and equipped with temperature detectors which operate an alarm if the temperature of any bearing exceeds a predetermined value. Brakes are provided under the rotor designed to bring the unit to rest in 15 minutes after water has been shut off the turbines, although normally each unit is stopped by a jet of water projected onto the back of the turbine buckets. The brake mechanisms can also be utilized as hydraulic jacks to lift the rotor off the thrust bearing to permit adjustments or maintenance of the component parts of the bearing.

Figure 15. View of transmission line indicating rugged nature of country traversed

Each main exciter is rated 250 kw, 250 volts, and the pilot exciter 10 kw, 250 volts.

Figure 10 shows a cross section of the powerhouse through number 2 unit.

Transformers

Main transformers are 3-phase and match the generating units in capacity. Each is rated 50,000 kva, 13.8-kv delta to 230-kv Y with high-voltage neutral solidly grounded. The high-voltage winding has full capacity taps at 250, 240, and 220 kv and one of reduced capacity at 210 kv. Two forced-oil water-cooled heat exchangers per unit external to the transformer provide the necessary cooling, each cooler alone being capable of keeping the transformer in operation at three-quarter load. The heat exchangers are located below the transformers and the oil pressure inside the transformer normally is adjusted to exceed the water pressure, thus reducing the possibility of water entering the transformer in the event of a leak developing in the water piping.

These 3-phase transformers, complete with oil, weigh 171 tons each, both weight and dimensions being practically the maximum which could be transported to the site.

Switching and Control

Figure 12 is a 1-line diagram of the station. On the low-voltage side of the transformers it will be noted that a circuit breaker and a separate station service transformer are provided for each unit. The switchgear is of metal-clad type with an oil circuit breaker of 15 kv, 3,000 amperes, 1000-megavolt-amperes interrupting rating. The service transformers are 3-phase, 300 kva with load ratio control on the primary supplying 460 volts for the normal operation of all auxiliaries. Provision is made on the secondary side for synchronizing with the station service supply so that station service can be supplied from any generator or, alternatively, the auxiliaries of any unit can be operated from the separate station service supply, should this be required. The station

Figure 16. An indication of the transmission line maintenance problems

service supply is presently obtained through a 2,300/460-volt step-down from a small 4,000-kva hydrogenerating unit, which was installed some years ago adjoining the new plant for construction power and local service.

The main transformers are located in the switchyard behind the powerhouse. The leads from the low-voltage switchgear are 150 feet long in underground ducts and consist of two 2,500,000-circular mil lead-covered cables in parallel on each phase.

The high-voltage side of each transformer is connected through a motor-operated disconnecting switch to a 230-kv ring bus with four oil circuit breakers, as shown in the 1-line diagram, Figure 12. The insert in Figure 12 indicates present plans for the ultimate development when all ten units are installed, which makes provision for four outgoing transmission lines. At this stage two generating units through their individual transformers are connected to one position in the ring.

The 230-kv oil circuit breakers are operated by compressed air and rated 800 amperes with an interrupting rating of 3,500-megavolt-amperes and a fault clearing time of three cycles.

Protective Relaying

Each generator is provided with split-phase, differential, and overspeed protection with an impedance relay connected for stand-by. This relay has a double set of elements with each set supplied from a separate source of potential to prevent operation should potential in one set of elements be lost for any reason, such as blowing of a potential transformer fuse.

Each main transformer has phase-differential and ground-differential pro-

tection with an impedance relay for phase stand-by, also of the double element type, and an over-current relay for ground stand-by. A gas pressure relay is fitted into the cover of each transformer tank to disconnect the transformer from generator and line if an arc or explosion should increase the oil pressure rapidly.

For protection of the transmission line, impedance relays are installed on the phases and directional overcurrent relays for ground-fault protection controlled by carrier-current equipment of standard type which also blocks tripping of the line under out-of-step conditions. Overcurrent relays of the nondirectional type are used for stand-by ground protection. The respective relay zones are indicated by the dotted lines in Figure 12.

Figure 18. La Joie Dam under construction showing stream flow diverted through tunnels

TRANSMISSION LINE

The main feature of this line is the rugged nature of the country through which it passes which posed various access and construction problems. Leaving the power plant, the line follows the route of the Pacific Great Eastern Railway along the shore lines of Seton and Anderson Lakes westward, then up the Gates River Valley across the main divide of the Cascades and down the Birkenhead River Valley to cross the Lillooet River at Pemberton, then up the Green River Valley over a further divide in the vicinity of Alta Lake, down the Cheakamus River traversing the Cheakamus Canyon to tidewater at Squamish. After following the rugged shore of Howe Sound for some 10 miles it turns inland up Furry Creek to cross into the valley of the Capilano River, thence down that valley across the top of North Vancouver Municipality to the Second Narrows over Burrard Inlet to Vancouver City.

A total of 704 steel towers is utilized between the power plant and Horne-Payne Substation, the actual distance being 126.88 miles. The maximum and minimum spans are 2,500 and 192 feet respectively, with an average span of 960 feet. A right-of-way was acquired of sufficient width to accommodate a second circuit at a later date. Single-circuit towers have been utilized for the greater part of the route, therefore, on this initial line, except where it is not practicable to construct two parallel tower lines when double-circuit towers have been used. There are 49 such double-circuit towers at the Vancouver end of the line where it traverses built-up areas.

The conductor is a 795,000-circular-mil steel-reinforced aluminum cable utilizing 54 strands of aluminum on 7 strands of

Figure 17 (left). Plan and elevation of La Joie Dam

Figure 19 (below). La Joie Dam under construction showing facing

steel, and having an over-all diameter of 1.093 inches strung with a horizontal spacing of 26 feet. Transpositions at 6- to 12-mile intervals are relatively frequent, as the line parallels communication circuits along the Pacific Great Eastern Railway for the greater part of the route. Sixteen 11,000-pound insulator units are used per suspension string and sixteen 25,000-pound units for strain purposes. As lightning is relatively infrequent in the areas traversed, ground wires are installed for a short distance only at the power plant and receiving station.

Construction of the line was begun in June 1946 and completed in October 1948. To complete it in this time it was necessary to carry on tower erection all through the winter of 1947–48 in the face of all sorts of weather conditions. In spite of the close proximity of the railway from Squamish to the power plant, 142 miles of access roads were built in connection with its construction. Experience is presently being obtained with maintenance of the line; one of the various factors which has to be considered is the heavy seasonal precipitation in the coastal areas which not only results in rapid growth of brush and tree cover but frequently causes slides and swells the rivers and streams with resultant washouts of bridges and maintenance roadways. Keeping such roadways open in deep snow in some of the rugged narrow valleys also presents a problem. A helicopter is used regularly for inspection of the line and 4-wheel-drive jeep trucks for ground patrol.

Storage Dam at La Joie Falls

Reference was made previously to the high ratio of maximum to minimum flow of the Bridge River, making it necessary to provide storage facilities to operate the plant at the required load factor during the season of restricted runoff. For the initial stages of development, these storage facilities are provided on the upper valley of the Bridge River. After investigation of several sites, a storage dam was chosen at La Joie Falls, approximately 35 miles above the diversion tunnel intake.

The ultimate dam at this site will be approximately 275 feet in height above the original river bed, 3,500 feet along the crest with a width of 680 feet at the widest part of the base, and will impound 570,000 acre-feet of water. The extent of the ultimate dam is shown by the broken lines in both plan and elevations in Figure 17. The crest will be at an elevation of 2,472 feet.

The first stage contemplated for use with these generating units is shown in heavy lines in Figure 17 with a crest elevation of 2,395 feet. This is a rock-filled structure approximately 1,450 feet long on the crest, with maximum depth in the river bed of 200 feet, a maximum width on the base of 470 feet, and having a slope of the upstream face of 1.3-to-1, downstream face of 1.4-to-1. Foundation offers no problem at this site.

Preparatory work of erecting a camp and clearing the dam site was begun in June 1947. In September, excavation of the discharge channel for the diversion tunnels was commenced and was followed by excavation of an intake channel and the excavation of the spillway channel. Driving of the two parallel diversion tunnels began on March 9, 1948. These tunnels are 645 feet in length, driven 17 feet and lined to 14 feet inside diameter. At the outlet end, the last 72 feet of tunnel was lined with steel pipe one inch in thickness, which provides for a reduction in size from each 14-foot diameter tunnel to two 4-foot diameter Howel Bunger valves. The final reducer section from 10-foot diameter to 4 and the Bunger valves were not installed at that time, however, as it was later necessary to divert all of the spring runoff through the tunnels while the placing of the dam foundations in the old river bed was carried out.

At the intake end the foundation for a gate structure was built and this structure was raised in 10-foot lifts. After construction of a coffer dam 700 feet in length to a 2,284-foot elevation, the river was diverted on February 11, 1949, to the first tunnel and later to both tunnels as the runoff began to increase.

In the meantime, quarrying operations had been going on at a site about one mile northeast of the dam. This site had been chosen after study of the geological features of the area as the best source of a suitable supply of rock fill for the dam. To obtain this rock, which is an augite diorite, it was necessary to build 7,000 feet of roadway suitable for heavy traffic between quarry and dam site. Wastage from the quarry was utilized to a very considerable extent for this purpose.

As it was essential that some storage be provided for the 1949–50 winter season the work of placing the rock fill was pressed during the spring and early summer months. As originally designed, the dam was to be sealed on the upstream side by a reinforced concrete paving keyed into the foundation rock at the toe of the slope. However, a timber facing was substituted for the concrete facing, which substitution was considered desirable in view of the fact that facing would have to follow immediately on the rock fill without any time for settlement. The timber sleepers for this facing were placed vertically, the facing planks 4 by 12 inches were placed horizontally in two layers with lean concrete placed between the sleepers to provide support for deck planking, and underneath, where the unevenness of the rock fill required it.

Storing of water commenced in mid-August 1949, and for the next six weeks the water level rose steadily, following closely on the placing of the facing. On October 23, all work was suspended. Rock fill had been placed to a 2,370-foot elevation, involving in all some 572,000 cubic yards; the intake concrete was completed to an elevation of 2,370 feet and the dam capable of storing water to an elevation of 2,365 feet. Maximum water level was reached on December 20 at a 2,356-foot elevation.

Preparations are being made to recommence operations and a decision recently has been made to increase the height of the dam to beyond the 2,395-foot elevation visualized in the stage indicated in Figure 17 to permit storage of water to an elevation of 2,405 feet. This may call for some revision of the plans in so far as the location of the spillway is concerned, and will require increasing the spillway height above the planned 2,380 feet of the initial stage.

Future Development

The raising of La Joie Dam to its ultimate level of 2,472 feet to provide 570,000 acre-feet of storage will coincide with the installation of units Number 4 and 5 at the Bridge River Plant. These units can be accommodated by the present diversion tunnel through Mission Mountain, but will require construction of additional transmission facilities to the load area.

For the next stage a second diversion tunnel as large or possibly slightly larger than the existing one to supply units 6 to 10 will be required. The storage required for year-round operation of these units will be provided by the lower storage dam previously referred to. Choice of a final site for this lower storage dam has not been made, although considerable study has been given to the subject.

A location almost immediately below the present diversion dam has much to offer in that the canyon walls would lend themselves to a dam of relatively short crest length, but there exists the foundation problem referred to in connection with the diversion dam. Experience with this present dam during the next several years will doubtless aid in

assessing the foundation requirements of a higher dam at this point. Another possible site exists two miles farther down the river, but such is the fall in the river bed that to obtain an equivalent amount of storage would necessitate a 130-foot higher dam. A site above the intake also has been given some study. As the valley is considerably wider in this locality, however, a dam of considerably greater volume would be required and there would be a sacrifice in ultimate head on the plant at Seton Lake.

In so far as transmission is concerned, as noted previously, the switching structure at the plant is laid out with space provision for four outgoing circuits. There are three possible routes for the three additional circuits. At some stage a second line will be built on the route of the existing line, as this is the shortest route to the load area. Two other routes remain, one eastward along Seton Lake and Seton Creek to the Fraser River and down through the Fraser Canyon to the Lower Fraser Valley; the other westward, paralleling the existing line as far as Pemberton, then south paralleling Lillooet Lake and Lillooet River and via Harrison Lake to the same termination. Studies of the various factors involved have not been carried sufficiently far at this time to determine whether both or only one of these routes will be utilized.

Conclusion

A few words with regard to the system of which the Bridge River Development forms a part may be of interest in concluding this paper. The total generating capacity on the British Columbia Electric Lower Mainland system now is 313,600 kw in six hydroelectric plants. Two additional projects are presently under development, a Number 3 unit of 35,000 kw at Ruskin on the Stave River, and the replacement of seven small units in the Buntzen Number 1 plant with a new 50,000-kw unit, the combined effect of which will be to increase the system peaking capability to 377,600 kw by October 1951.

Since mid-1949, surplus power above system load requirements at a monthly rate of 15,000,000 kilowatt-hours or more has been transmitted to a group of other member utilities of the North West Power Pool over a 230-kv interconnection from Vancouver to Arlington, Wash.

No Discussion

Hydroelectric Generator Excitation Experience at Grand Coulee

C. L. KILLGORE
MEMBER AIEE

N. G. HOLMDAHL
MEMBER AIEE

THE Grand Coulee Power Plant located in central Washington is the largest concentration of hydroelectric generating capacity in the world, having a presently installed capacity of 1,316,000 kw and an ultimate capacity of 1,974,000 kw. This plant is being built and operated by the Bureau of Reclamation as a major feature of the Columbia Basin Project.

The Grand Coulee Power Plant differs from most modern hydroelectric plants in that only 12 of its 18 108,000-kw main units have direct-connected exciters, while the other six, which are to be used to drive 12 65,000-kw synchronous pump motors as well as to furnish commercial power, have separate motor-driven exciters. Since these six main units have exciters whose motors are driven by two 10,000-kw station-service generators, the problem of loss of generator excitation is an important consideration. This paper covers the experiences obtained from consideration of the original power layout for these exciter motors and the development of the final plans for insuring the power supply to these motors. It also covers experiences with loss-of-field relays and excitation under heavy load rejections.

Motor-Driven Exciters

The 6,900-volt station-service system consists of two 10,000-kw station-service generators feeding into a complete 6,900-volt double-bus system with double breakers for all generators and all feeders. The feeder breakers are controlled so that only one breaker can be closed at a time unless the busses are paralleled through a generator breaker. In that case both feeder breakers can be closed momentarily in order to transfer a feeder from one bus to the other. The exciter motors for generators *L-1* through *L-6* are fed from the switchgear. In the early years of operation when these six units were the only ones installed, or, even now, when they still form a major portion of the generation, loss of excitation on the units constituted a major outage, not only to this plant but usually to the Northwest Power Pool, of which this plant forms a part. Because of this potential hazard to the system, considerable study was given to the problem of insuring the power supply to the exciter motors. Station-service generator differential relays were moved to a location where there was little chance of accidental tripping. Also, the control system was changed so that the exciter feeder breakers would automatically transfer from one 6,900-volt bus to the other in case of loss of potential on the feeder. This scheme offered protection should a bus fault or failure of the station power source occur, or should a feeder breaker fail to clear. As the exciter motors are synchronous, across-the-line starting, and rated at 600 horsepower and 6,900 volts, considerable experimenting was done to determine the effect of dropping the loaded exciter from one bus and picking it up on another. This automatic transfer was tested under variable conditions of main generator load, the results of which are shown graphically on Figures 1, 2, 3, and 4. Figure 1 illustrates the effect of transferring the exciter motor without any load on the exciter, while the others show the effect with various conditions of load on the main generators.

The following information is pertinent to the proper interpretation and evaluation of the oscillograms. Under normal starting of the exciters, the machine is closed in on the 6,900-volt system with the motor field short-circuited. The machine comes up to a speed as an induction motor, and after a predetermined length of time necessary for the pilot exciter voltage to build up (about 13 seconds), the motor-field circuit breaker is closed, connecting the pilot exciter output to the field of the motor. The motor pulls into synchronism with a minimum of disturbance upon the application of the field. The high motor current on the oscillograms for such a long period, after closing the unfaulted breaker and then the reduction to the initial valve, is caused by the machine being run as an induction motor for about 13 seconds before application of the field.

It will also be noted that the exciter-motor voltage does not exhibit rapid decay until about ten cycles before the motor is closed-in on the opposite bus. This is caused by the motor operating as a synchronous machine with its field breaker still closed until the undervoltage relay operates and trips the breaker connected to the faulty 6,900-volt bus. This action in turn trips the motor field thereby causing it to act as an induction generator rotated by the kinetic energy of its rotor.

From the oscillograms, it was determined that an exciter motor-generator set could be removed from one power source and closed in on another without requiring removal of the main generator from the system. The controls on the exciter sets were then changed to incorporate this feature on all of the six units containing motor-driven exciters.

However, this arrangement was not entirely satisfactory as the control circuits were somewhat complicated because a number of control switch and relay contacts are required to operate in

Paper 50-137, recommended by the AIEE Power Generation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 13, 1950; made available for printing April 10, 1950.

C. L. KILLGORE is with the Bureau of Reclamation, Denver, Colo.; N. G. HOLMDAHL is with the Bureau of Reclamation, Coulee Dam, Wash.

Figure 1. Automatic transfer of *L*-5 exciter motor from upstream to downstream station-service bus with zero load on main unit, Grand Coulee Power Plant

Figure 2. Automatic transfer of *L*-5 exciter from upstream to downstream station-service bus with 25-megawatt load on main unit

the correct sequence. Then, too, the problem was affected by the decision to install a ring bus for all main units at Coulee[1] and by plans to install the third 10,000-kw station-service generator for commercial and local power. The ring bus affected this problem because the system was designed so that ultimately a loss of one 230-kv bus section (three units and two transmission lines) would not cause instability on the system. Under that condition, the loss of three exciters together with the loss of their three associated generators would not be as serious as it was when these units formed the major portion of the plant's capacity. The addition of the third station-service generator to the plant also eased the loss-of-excitation problem because it added another source of supply for the exciter motors and thereby decreased the probability of loss of power source. By using the surplus power from these generators for local and commercial use, some additional hazard was added because of the connection of the station-service system to the main transmission system. This additional hazard was partially compensated for by having two additional power sources in case of loss of the station-service generators. As a protection against the main system speed swings, an over-and-under-frequency relay will be

Figure 3. Automatic transfer of *L*-5 exciter motor from upstream to downstream station-service bus with 104-megawatt load on main unit

Figure 4. Automatic transfer of *L*-5 exciter from upstream to downstream station-service bus with 129-megawatt load on main unit

installed on feeders *0* and *23*, which connect the station-service bus to the main transmission system, so that the main power system and the station service will be separated in the event of any major system speed fluctuation. The third station-service unit, together with the autotransformer banks for transmitting the excess power, are scheduled for installation in 1950. In the meantime, both busses are operated in parallel with both generator breakers closed, with three exciters on each bus, and with the automatic transfer in operation.

Loss-of-Field Relays

As originally designed, the Grand Coulee units were equipped with differential relay protection only. It was foreseen that the loss of field on a main unit would cause the unit to go out of step as the field decayed, resulting in some voltage disturbances as well as producing large currents in the damper windings and field windings of the generator rotor. Such a condition might continue for an appreciable length of time before the unit was either removed from the system or the field restored, thereby causing considerable damage. System disturbances from such loss of field might be serious if it occurred at time of heavy loads. It was to protect against these possibilities that loss-of-field relays are being installed on all main units. In order to in-

Figure 5. Effect of reducing field until main unit pulled out-of-step with the system

stall a loss-of-field relay, which would trip a unit if the field reached a value where it could not remain in synchronism, an actual test was made on a main unit. Figure 5 is an oscillogram made when the generator field was gradually reduced until the fully loaded machine pulled out of step. It was found that on these units which have a rated voltage, open circuit field current decreased to about 700 amperes. From these data, it was decided to set the loss-of-field relay to pick up at 800 amperes of field current, a condition which should not be met in normal operation unless there are extreme overspeeds or actual loss of excitation. The relays are of the undervoltage type, are controlled from the main generator field voltage, and use the pilot exciter voltage to set up the opposing field necessary to develop torque on the relay. There have been no operations of this relay in service as it has only been in operation since June 1949. During load rejections of 75 per cent load and greater, when the unit has been separated from the system or the unit is free to go over rated speed, this relay will pick up. However, such operation is blocked by a contact on the governor which is open at 20 per cent gate and below.

Referring to Figure 5, it will be noted that at the point of pull-out, the generator voltage was reduced to 7,400 volts from a normal of 13,800 volts, and the generator current increased to 14,800 amperes from a normal of about 5,200 amperes.

Experience with one unit with non-connected damper windings, when its field was lost while carrying full load, indicates that the unit will reach about 25 per cent overspeed before the governor can recover and reduce the wicket gate opening and turbine output to the value which can be carried as an induction generator.

Generator Voltage Regulation During Disturbances

During the initial test period of each unit at the Grand Coulee Plant, a series of tests of load rejections were made to determine the operation of the governor, the pressures developed in the penstock due to hydraulic surges, and the operation of the voltage regulating equipment. Rejections of full load during such tests and during commercial operation cause the generator voltage to rise considerably and to reach a value some 30 per cent above the rated voltage. Although this rise in itself should not cause any undue harm to equipment in first-class condition, this overstressing of insulation should be eliminated or reduced if possible. A certain amount of voltage rise cannot be prevented because, as soon as the electric load is removed, the voltage will rise to a point on the open-circuit saturation curve for the machine. Also, for direct-connected exciter machines, the speed of the pilot exciter, main exciter, and main generator rotors will begin to rise rapidly which will cause a corresponding generator voltage increase. Voltage-regulation equipment should be designed to compensate for these voltage changes within reasonable limits.

Recently, the installation of a Silverstat regulator in the pilot exciter field

Figure 6. Maximum load rejection test on main unit, left powerhouse

Figure 7. Maximum load rejection test on main unit, right powerhouse

has caused the pilot exciter voltage to remain practically constant during system disturbances as can be seen by a comparison of the traces shown in Figures 6 and 7.

Figure 6 shows load rejection of a unit which has the normal type of pilot-exciter voltage regulation, namely, an overvoltage relay which inserts a block of resistance in the pilot exciter field at a predetermined pilot exciter voltage. The repeated operation of this relay accounts for the zig-zag shape of the pilot exciter voltage trace. Figure 7 is a test on a similar unit but has a continuous step regulation of the pilot exciter field. Practically uniform pilot exciter voltage is maintained throughout the various speed changes of the unit. This factor helps to reduce the peak of the main generator voltage by reducing the amount of pilot exciter voltage available to supply excitation to the main exciter. In each case the unit was separated from the system while carrying a load of 130 megawatts. The generator voltage rises immediately to the open-circuit saturation curve, and then gradually rises further as the rotor speed increases due to the time required for the turbine gates to close from wide open to the speed-no-load point. The time for such operation is four seconds. However, as soon as the voltage rises over 0.5 per cent, the main exciter rheostat control on the voltage regulator attempts to bring the voltage back to normal.

At two per cent above the rated voltage the high-speed lowering contact on the regulator operates to insert a block of resistance in the main exciter field. This action accounts for the first step in the main exciter voltage after separation from the system. The high-speed lowering relay then remains energized continuously until the voltage is reduced to about ten per cent above normal when intermittent operation begins.

From analysis of tests made to date on three units with the overvoltage relay-type of pilot exciter voltage control against the continuous regulation type of control, it appears that peak voltages have been reduced about 1.5 kv to a maximum of about 16.5 kv. However, the peak voltage reached will depend upon the amount of excitation just prior to the loss of load.

Analysis of these oscillograms also indicates that the main exciter voltage reduces to a practically constant value during the overspeed, which condition is believed to be caused by the resistance controlled by the high-speed lowering regulating relay not being large enough to further reduce the main exciter voltage.

It is planned to run further tests on this phase during load rejections on a future machine. Additional resistance will be inserted in the main exciter field in an attempt to further reduce the main exciter voltage and thereby reduce the generator terminal voltage. However, it does not appear that the peak voltage will be reduced very much because of the time necessary to operate the generator voltage regulator and the time necessary for the main generator field to decay.

Summary

1. Experience with the motor-driven exciter at the Grand Coulee Power Plant

indicates that automatic transfer of power sources to the motor can be successfully done under full load by removing the motor from a faulty power source and reconnecting it to another power source.

2. However, experience also indicates that the best protection is to provide sufficient power sources so that the loss of one source will not cause the loss of excitation.

3. Additional pilot-exciter voltage-regulation equipment has reduced peak voltages on the generators approximately 1.5 kv on a 13.8-kv base with the possibility of reducing this still further by the addition of more resistance in the high-speed lowering relay circuit in the main exciter field.

Expansion of the System of the Southern California Edison Company

A. A. KRONEBERG
FELLOW AIEE

THE BEGINNING of the Southern California Edison Company's system may be traced back to 1893 when two 250-kw 2,200-volt generators were installed for local use near Redlands, Calif., approximately 75 miles from Los Angeles. From this small beginning the company expanded to become one of the ten largest privately-owned electric utilities in the United States. The company's system serves directly some 75 incorporated cities and 150 unincorporated communities and outlying rural territories. It also supplies electric energy to four municipalities for redistribution and to other utilities on a wholesale basis. The territory served includes large areas devoted to farming and fruit growing, which are made possible by irrigation. Among the more important industries served are those engaged in the production and refining of oil, production of motion pictures, fruit packing, the manufacture of cement, rubber tires, chemicals, airplanes, oil-well equipment, automobiles, and the production and fabrication of iron and steel. In addition, the company serves two electric railway systems operating in and around the city of Los Angeles.

The expansion of the company's system is the direct result of population growth in southern California. Figure 1 shows this growth of population in the present service area of the company during the first half of the twentieth century. Population figures for 1900, 1910, 1920, 1930, and 1940 were obtained from the Federal census reports and are accurate. Population figures for other years were estimated on the basis of average daily attendance records of school districts. It may be noted that the population approximately doubled during each decade except during that from 1930 to 1940. This rapid growth of population is due to immigration and was but temporarily retarded by the depression of the 1930's. The primary effect of the population growth is an increase in the number of customers. One metered service is required for every three people. Thus it is estimated that by the end of 1950, the company will be serving a population of approximately 3,000,000 through nearly 1,000,000 meters. The per capita use of energy also is showing a growth which, although adversely affected during the decade of 1930–1940, resulted in a net increase from 1,600 kilowatt-hours in 1920 to more than 2,500 kilowatt-hours in 1949. Figure 2 illustrates the total annual energy use in the service area of the company.

The maximum demand upon the generating facilities of the company also has grown at a comparable rate. However, a substantial improvement in annual load factor took place concurrently with expansion of the system. This improvement is due to greater diversification of energy use. From an estimated 40 per cent in the early years of the system's growth, the annual load factor improved to 50 per cent in 1920, to 60 per cent in 1930, and to 65 per cent in 1949. Figure 3 illustrates the maximum demand in the service area of the company.

Generating Capacity

Two alternatives are available to the company in providing generating capacity for supplying this rapidly growing load. One is the continuation of the development of the upper San Joaquin River which is known as Big Creek, and the other is the construction of steam-electric plants at the load. A brief review of the development of the major generating sources follows. The development of the upper San Joaquin River was begun in 1913 with 64,000 kw of hydroelectric generator capacity in powerhouses number 1 and Number 2. From then until 1928, the chain of Big Creek powerhouses was increased to five with nearly 400,000 kw of generating capacity. The plans of development at that time contemplated an ultimate project of 18 powerhouses, totaling approximately 1,070,000 kw of capacity. Operating experience of 1924, the year of minimum water resources in the history of the Southern California Edison Company, demonstrated the need of balancing hydroelectric developments in California with steam-electric plants of no less capacity than 40 per cent of the hydroelectric plant capacity. The rapid improvement in steam plant economy during the decade from 1920 to 1930, and the concurrent decline in price of fuel in southern California, caused the company to defer, in 1928, the further development of the Big Creek hydroelectric project. Revised plans at that time contemplated the construction of the Long Beach Number 3 Steam Plant which was designed for an ultimate capacity of 800,000 kw. The business depression of the early 1930's halted this development after two 100,000-kw units had been completed and placed in operation. With the older steam plants in operation on the system, this addition provided 465,000 kw of steam plant capacity to be combined with a total hydroelectric capacity of 493,000 kw in operation at Big Creek and in miscellaneous river flow plants on the system of the company in 1931.

In 1939 the company began receiving power from the Hoover powerhouse of the United States Bureau of Reclamation.[2] Under the terms of various con-

Paper 50-138, recommended by the AIEE System Engineering Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 3, 1950; made available for printing April 10, 1950.

A. A. KRONEBERG is Senior Electrical Engineer with the Southern California Edison Company, Los Angeles, Calif.

Figure 1. Population in the territory served by the Southern California Edison Company

tracts with the Bureau of Reclamation, the company operates a part of the powerhouse as an agent of the government, and receives and pays for energy allocated to it. In addition, the company is entitled to receive and pay for 40 per cent of energy allocated to but not used by certain other allottees, and is entitled to receive and pay for 40 per cent of surplus energy (secondary). The maximum capacity of the portion of the Hoover powerhouse connected to the system of the Southern California Edison Company directly and through the transmission system of the Metropolitan Water District of Southern California is 465,000 kw.

The additions of generating capacity to the company's system since 1945 include gains in capacity of old generating units due to the change of system frequency from 50 to 60 cycles,[4] the addition of a 35,000-kw unit at Big Creek Number 3, the addition of Redondo Steam Plant having an operating capacity of 280,000 kw, and the construction of Big Creek Number 4, now under way, which is expected to add 84,000 kw to the 1,730,000 kw of capacity in operation on the company's system on January 1, 1950. For planning purposes, this installed capacity must be discounted by: (a) hydroelectric capacity rendered idle by deficiency of river flow; (b) hydroelectric capacity rendered idle because of shortage of water in storage reservoirs; (c) generating capacity removed from service for maintenance and repair; (d) prudent reserve. The remaining capacity is the capability of the system in a dry year and must be expanded to remain equal to the expected maximum demand of the load.

Transmission System

The transmission system of the Southern California Edison Company is an interconnection of 220-kv transmission lines linking the Big Creek hydroelectric plants, the Hoover powerhouse of the United States Bureau of Reclamation, and the steam plants.[1] Two 106,000-kw 60-cycle steam-electric units at the Long Beach Steam Plant Number 3 are directly connected to the 220-kv transmission lines.[2] All other steam-electric units are connected to 66-kv subtransmission systems which in turn are connected to the 220-kv system through 220/66-kv transformers. Figure 4 is a map of the company's transmission system showing existing plants and lines, authorized plants and lines under construction, the 220-kv line of the Metropolitan Water District of Southern California, and the service area of the company.

This transmission system evolved from the two parallel 150-kv 240-mile transmission lines constructed in 1913 for transmitting Big Creek power to Southern California. At the time these lines held the distinction of being the longest lines in the world and of being operated at the highest voltage. In 1923, following the lead of the Pacific Gas and Electric Company, the voltage of these lines was changed to 220 kv, the towers were raised to provide added clearance to ground, insulators were added, and 220/150 kv autotransformers were connected at the terminals to maintain connections with existing equipment. The load-end terminals of the lines were connected to a grid of 66-kv transmission lines interconnecting the distribution substations of the company. With the growth of the system, the duty on 66-kv oil circuit breakers exceeded their interrupting capacity and many explosions and station fires occurred from time to time. This led to the adoption in 1928 of the fundamental principle underlying the planning of the system and its operation.

Figure 2. Energy generated for use in the service area of the Southern California Edison Company

Figure 3. Demand on generators in the service area of the Southern California Edison Company

This principle is the establishment of a "backbone" transmission system from which a number of subtransmission systems are supplied through 220/66-kv transformer banks. Except for having only the 220-kv system as a common source of supply and having some emergency 66-kv tie lines to adjacent systems, each one of these subtransmission systems is independent of the other. From some four such systems originally obtained by splitting the 66-kv grid into sections, the number of subtransmission systems and areas served by them has increased to 13. The number of major substations supplying subtransmission systems has increased from three in 1924 to 12 in 1949. The purpose of this is to limit to 225,000 kva the capacity of 220/66-kv transformers operating in parallel to a short circuit (12 per cent impedance). The effects of system growth upon the interrupting duty of circuit breakers and the resultant program of modernization and replacement of circuit breakers are confined to the 220-kv transmission system by this method of expansion and system operation.

The capacity of each 220-kv transmission line is nominally 200,000 kva, but the normal loading is not in excess of 165,000 kva for reasons of stability of operation. The system is planned for operation near 75 per cent of the steady-state stability limit when all the equipment is in service. Coupled with the program of modernization of circuit breakers, this makes the system stable during all but the most severe 3-phase short circuits that occur on the system. It also is possible under this method of loading to remove from service occasionally, sections of line for repairs and rebuilds without curtailing generation. In addition to the 12 transformer substa-

tions, three switching stations are provided at the approximate mid-points between the three major sources of generation. The purpose of these stations is to limit the length of line sections to a maximum of 140 miles for stability reasons and to provide facilities for high-voltage interconnections with other systems.

Distribution

The term "distribution" in its broader meaning includes subtransmission systems, transformer substations, high-voltage distribution lines, primary distribution lines, line transformers, and secondaries. Each of these groups of system equipment must be expanded at approximately the same rate as the expected growth of load to maintain the established standards of service, quality, and continuity, to retain existing margins in load carrying capacity and thus to be prepared for sudden local load increases, and to provide for safety of employees and the public.

Figure 5 presents a diagrammatic summary of capacity of transformers interconnecting the various groups or systems of the Southern California Edison Company as reported on January 1, 1950. Some 1,190 megawatts of generating capacity is connected directly to the 220-kv transmission system. From the 220-kv transmission system, power is delivered to the 13 subtransmission systems through 220/66-kv transformers totalling 1,750 megavolt-amperes. The excess of step-down capacity over the capacity of generators is due in part to seasonal diversity of load in the various subtransmission systems and in part to capacity required to interconnect local generation with the 220-kv system, and to provide standby for this generation from the 220-kv system. Included in the subtransmission group is a small 33-kv system which is an extension of one of the 66-kv systems through autotransformers totalling 60 megavolt-amperes.

From the several subtransmission systems, power is delivered directly to ten large industrial customers, to one municipality for resale, to primary distribution systems (4 and 7 kv), and to high-voltage distribution systems (11 and 16.5 kv). The total stepdown capacity of 1,900 megavolt-amperes indicates a diversity of 1.1 in relation to the total generating capacity of 1,730 megawatts, and a diversity of 1.52 with respect to the "net" system peak of 1949, the latter being the demand in the service area of the company only. Approximately three-fourths of the stepdown capacity from the subtransmission systems is to high-voltage distribution. The high-voltage distribution systems are divided into two voltage groups. The service area within 50 miles of the Pacific Ocean and to the west of the 220-kv transmission system is served at 16.5 kv; while all the remaining area is served at 11 kv. Approximately one-third of the transformer capacity connected to the high-voltage distribution systems is installed at distribution substations stepping down to primary distribution voltage (4 kv). The other two-thirds of transformer capacity are supplying customers directly through customer substations or through line transformers. The prevailing arrangement of all distribution systems is that of radial feeders with occasional loops and double line arrangements when serving larger distribution substations. Primary distribution is used in cities and towns. A total capacity of 1,030 megavolt-amperes of transformers is installed at substations supplying primary circuits. Some 1,260 megavolt-amperes of line transformers supply customers from the primaries, indicating a diversity of 1.22 in primary distribution systems. The over-all annual efficiency of the system is 85 per cent. It has been raised slowly to this value from 80 per cent in 1929.

Reactive Power Supply and Demand

When power is transmitted through the inductive circuits of a power system, there is created a demand for reactive power which is similar to the real power losses in the system. Such a demand also is created in customer's equipment beyond the meter. This demand is in part composed of the magnetizing current taken by ironclad machines such as transformers and induction motors, and in part of the I^2X loss in series impedances. This demand must be supplied from sources of generation of reactive power in much the same manner as real power is supplied from generators. The company long ago abandoned the use of power factor meters as a means of control of reactive flow and instituted the metering and dispatching of reactive power on its system. The chief source of generation of reactive kilovolt-amperes on the system is synchronous condensers, operating on the 66-kv busses of the major substations. At the conclusion of World War II, the synchronous condenser capacity at the major substations was deficient by some 200 megavars (mvar) because no additions could be made during the war. Because of this deficiency, the required reactive power had to be generated on power generators and on frequency changers. To do so required operation of transmission lines on voltage gradients much steeper than originally intended, and operation of transformers on taps of

Figure 4 (left). Transmission system of the Southern California Edison Company

Figure 5 (right). Summary capacity diagram of the system of the Southern California Edison Company

Figures in circles—megawatts

Figures in boxes—megavolt-amperes

lowest ratio. To remedy this shortage of reactive capacity, the following programs were undertaken:

1. A program of installing each year approximately 50 mvar of static capacitors on distribution lines was begun in 1947. As reported on January 1, 1950, 170 mvar have been installed on distribution lines and on substation busses. Installation of 50 mvar has been budgeted for 1950.

2. An increase in capacity of existing synchronous condensers was obtained incident to conversion from 50-cycle to 60-cycle operation. The initial total capacity of 583 mvar was thus increased to 674 mvar.

3. A total of 120 megavolt-amperes of frequency changer capacity was released following conversion of the system from 50 to 60 cycles. The net gain in synchronous-condenser capacity resulting from uncoupling the frequency changers has been 228 mvar.

4. Four synchronous condensers have been purchased for installation at major substations. Of the total 220 mvar ordered, one 60-mvar machine has been installed and placed in operation. The remaining three machines are in various stages of construction.

The system demand of reactive power in 1949 is estimated in round figures to consist of the following: (a) customer demand beyond meters—450 mvar; (b) magnetizing requirement of all transformers operating on the company's system—270 mvar; (c) series losses in subtransmission lines, distribution lines, and transformers—400 mvar; (d) series losses in 220-kv transmission lines—360 mvar; (e) series losses in generator transformers and 220/66-kv transformers—200 mvar. The total demand was approximately 1,680 mvar.

To supply this demand the company had the following: (a) synchronous condensers—962 mvar; (b) a frequency changer normally operated as a condenser, but retained as an emergency connection for three 50-cycle machines at Long Beach Steam Plant Number 1—60 mvar; (c) 170 mvar of static capacitors; (d) 400 mvar charging capacity of 220-kv lines; (e) 70 mvar charging capacity of lines in subtransmission systems.

Table I. Supply and Demand of Reactive Power on the System of the Southern California Edison Company in 1949

	Megavars
Generating Capacity	
Hydro plants	90
Steam plants	280
Synchronous condensers	1,022
Static capacitors	170
220-kv transmission lines	400
66-kv transmission lines	70
Total available	2,032
Demand	
Customer demand	450
Transformer magnetization	270
Distribution loss	400
Transmission line loss	360
Generator and 220-kv transformer loss	200
Total demand	1,680
Planned Additions to Generation	
Synchronous condensers	160
Static capacitors	50
Fourth Big Creek 220-kv line	65
Total addition	275

The above supply capacity totals 1,662 mvar. In addition to the capacity of facilities for direct generation of reactive power, the real power generators are capable of delivering some reactive power to the system without overload. Thus 90 mvar may be obtained from hydroelectric plants, and 280 mvar from steam-electric plants, bringing the total available capacity up to over 2,000 mvar. Table I illustrates the supply and demand of reactive power on the company's system. Therefore, it may be concluded that the company has overcome the post-war deficit in reactive generating capacity, has kept pace with the growth of reactive demand, and has provided for the growth of reactive demand during the next two or three years.

Conclusion

The first and foremost problem of a planning engineer is the expansion of the system to permit generation, transmission, and distribution of additional real power required by the growing load. The second problem is the expansion of system facilities to generate, transmit, and distribute reactive power required to permit transmission of real power. The supply of reactive power is inseparable from the problem of proper voltage control on the system. Voltage control of the company's system is exercised at three points along the route from generator to the customer meter. First, voltage is controlled at the generator terminals by well-known methods of excitation control. The second point of control is on the 66-kv busses of major substations. Tap changers under load are provided on nearly all 220/66-kv transformer banks, and synchronous condensers are installed at nearly all major substations. Voltage at generating stations and at major substations is maintained in accordance with established schedules, usually ranging from 69 kv during the day to 65 kv at the time of minimum load. The third point of voltage control has been brought as near as practicable to the customer using voltage-sensitive equipment. The 4-kv primary circuits are equipped with voltage regulators compensated beyond the feed point of the circuit, that is, the point where the circuit branches off in all directions.

The problems of relay protection and system operation are not a planning engineer's direct responsibility. However, the system he has planned must be operable and protectable. For this reason the planning of the system of the Southern California Edison Company has always stressed simplicity. A simple system is easy to operate, it is easy to protect, and in the long run, it is easy to expand.

Relaying Practices and Economical Switching Station Arrangements of the Bureau of Reclamation

W. A. MORGAN
MEMBER AIEE

R. W. WORLD
ASSOCIATE AIEE

THE high-voltage transmission systems serving the western half of the United States are characterized by longer line sections between substations than is common in the eastern half, where the population density is greater. The relaying of the power systems of the Bureau of Reclamation, United States Department of the Interior, presents, therefore, somewhat different problems than usual. It is the purpose of this paper to describe some of the relaying schemes used by the Bureau and the philosophy underlying them.

The Bureau has designed and constructed power plants having 3,054,400 kw of hydroelectric generating capacity, and 3,997 miles of transmission lines of nominal voltages from 33 to 230 kv. The generating units are as large as 108,000 kva, and the first power plant was put into operation in 1909. At most plants, the electric energy is made available as part of a multipurpose project which includes irrigation and flood control as mutual benefits. In recent years, the Bureau has also been designated as marketing agent for the energy developed at the power plants constructed by the United States Corps of Engineers in the Missouri River Basin, and transmission systems are being designed for this purpose by the Bureau. In addition, throughout the 17 western states, there are several thousand miles of high-voltage transmission lines, and many hydroelectric power plants, pumping plants, and substations under construction or authorized at the present time.

The Bureau has several isolated power systems, and a number of power plants interconnected with large power systems owned and operated by others. The transmission voltages are 230 kv, 161 kv, and 115 kv, in general, while the distribution voltages are 115 kv, 69 kv, and 34.5 kv. On some systems, the 115-kv lines are functionally transmission circuits, while on others the 115-kv lines serve as distribution circuits, as there are small substations connected to the lines without high-voltage circuit breakers. It is not economical to have a standard practice for such a diversified group of electrical installations. One of the objectives in Bureau power system designs is the obtaining of maximum amount of power system for the last expenditure. This is accomplished without jeopardizing the protection of equipment. So, in some designs, it has been recognized that transformer faults and high-voltage bus faults are a rare occurrence, and it is not worthwhile to try to sectionalize for such faults to prevent an interruption to service. However, when service reliability is paramount, two busses or the equivalent are used.

Power Station Relaying Practice

The diagram in Figure 1 shows a typical power plant arrangement as might be designed at the present time. A minimum of circuit breakers is used in the interest of economy, current transformer circuits are not transferred when the spare circuit breaker is used, and a line position in the switchyard is eliminated by putting the spare circuit breaker in one of the transfer bus positions of a transformer circuit. In this case, the spare circuit breaker is provided with a set of line relays connected to its bushing current transformers, and the relays may be used for any of the circuits by adjusting the settings. The spare circuit breaker is put in a transformer circuit position because of the low probability of transformer or generator faults, as a fault in the transformer circuit when the spare breaker is being used for a line circuit would interrupt both circuits.

Arrangements without a low-voltage bus for generators have been used at a number of the large power plants. Separate transformer and generator differential relays are always provided to gain the advantage of more sensitive and faster protection for the generator. Often the generator differential relay zone is overlapped by the transformer differential relays if the current transformer arrangement can be simplified by doing so. Standard-speed induction-type ratio differential relays almost always are used for both the transformer and generator differential relays, instead of high-speed relays requiring special methods of adding restraint to prevent tripping on inrush transients and heavy faults external to the protected zone. The standard speed relays are usually sufficiently fast to coordinate with 15-cycle time delay of remote line relays.

Experience has shown that the relays have operated properly for all major faults in station equipment and it is believed that backup protection against equipment faults is unnecessary in attended stations. The individual relay elements provide backup to each other as, usually, a heavy fault will pick up the relays in at least two phases. The use of overcurrent relays as backup protection is undesirable since a setting that is effective under fault conditions is likely to give false tripping under overloads, remote faults, or other system disturbances. However, gener-

Paper 50-140, recommended by the AIEE Relay Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted February 20, 1950; made available for printing April 10, 1950.

W. A. MORGAN and R. W. WORLD are both with the Bureau of Reclamation, Denver, Colo.

ator overcurrent relays are provided where necessary to protect otherwise unprotected zones resulting from use of current transformers for differential protection that do not overlap the circuit breaker, or where it is impractical to have differential protection on the station bus.

At smaller plants, the transformer differential zone sometimes includes the station service transformer, which is given no other protection. This, of course, is not selective protection but is considered adequate if a solid fault at the low-voltage terminals draws fault current in excess of relay operating current. At larger plants, separate differential protection or fuses are provided for the station service transformers. Thermal devices in the main generator and transformers are connected to give alarm only. Protection against overload is at the discretion of the plant operator.

The high-voltage main bus invariably is given differential protection with induction-disk overcurrent relays having short-time characteristics. These simple relays have been found satisfactory for reasons similar to those given for simple transformer protection. Linear couplers or other special bus differential relays are being considered for 230-kv busses where fault currents are unusually high, but, so far, calculations have shown that they are not required to prevent false operation and their advantage would be to give faster relay operation, if obtainable at no additional cost, complication or loss of reliability.

Bus differential relaying becomes complicated where the bus may be sectionalized and it is desirable to obtain selective tripping for all operating arrangements. In these cases, it has been thought desirable to find a way of omitting bus protection. A ring bus, as shown in Figure 2, is one way of eliminating the need for bus differential relaying where there are only a few circuits. The ring bus requires less switchyard space than a double bus. The ring bus may be more applicable to a load substation than a power plant switchyard, because the need for keeping the ring intact in order to retain proper selectivity in clearing faults has resulted in low-side generator circuit breakers at one power plant where the ring bus will be used. Also, the 3-winding transformer type of transformer differential relay has been found necessary since the maximum fault current through the high-voltage current transformers is large compared to the rated current of each generating unit.

Station-service power for large power plants such as Hoover, Grand Coulee, and Shasta, has been furnished by two or more relatively small hydroelectric generating units normally operated as a system entirely separate from the main generating units. However, at the smaller power plants, and in the designs of recent fairly large plants up to 300,000 kw in capacity, station power is obtained usually from the main power system by some variation of the scheme shown in Figures 1 and 2. An electrical interlock prevents paralleling the two generators through the station-service system, and, by means of undervoltage relays, load is automatically transferred from one generator to the other.

At some power plants with the unit system, the high-voltage bus differential relays are connected to shut down the generating units in addition to tripping all high-voltage circuit breakers; see Figure 3. This is necessary in order to protect the zones between current transformers located in the transformer bushings and circuit breakers and is considered preferable to the addition of other relays for the sole purpose of protecting these zones.

At power plants using the unit system but serving two transmission systems at different voltages, it has been our practice to furnish 3-winding transformers for some or all of the generating units. A disconnecting switch for each generator connected to a 3-winding transformer permits transfer of energy between the two transmission systems when the generator is not running.

The arrangement shown in Figure 3 is the result of a practice that has developed of avoiding the transferring of current transformer circuits in taking a circuit breaker out of service. A system of utilizing the spare circuit breaker in the transfer bus position by automatically transferring the trip circuit is used to economize on double circuit breakers. For example, if one of the line circuit breakers were to be taken out of service, the auxiliary switches, operating when that particular line transfer bus disconnect switch is closed, will connect the trip circuit for the line relays so that they would trip the circuit breaker in the spare or transfer bus position. Sufficient current transformers are provided so that no switching of current transformer secondary circuits is necessary. This usually requires wound-type current transformers in each line. However, an extra line position in the switchyard is avoided for the so-called bus-tie or spare circuit breaker, and, of course, double circuit breakers are not required.

Another arrangement which eliminates the necessity for transferring current transformer circuits without the expense of a full double circuit breaker installation is shown in Figure 4. In this case, the current transformers provided with the oil circuit breakers are utilized wherever possible and wound-type current transformers are installed in the vacant oil circuit breaker positions. This arrangement is used at Grand Coulee Power Plant where the cost of 230-kv 10,000,000-kva interrupting capacity circuit breakers made it desirable to consider a modification of the double circuit breaker arrangement.

The unit system has been used at a number of the large power plants with a trend toward 3-phase unit transformer banks where the physical size is within transportation limitations. Ground

Figure 1. Typical busing arrangement for a power plant using a minimum number of circuit breakers

Figure 2. Ring bus for a power plant using a minimum of circuit breakers; is applicable where there are few circuits

faults in the generator voltage system are detected by a voltage relay energized from a potential transformer or distribution transformer connected between generator neutral and ground. When a distribution transformer is used, a secondary resistor provides an in-phase component of fault current roughly equal to the reactive component due to capacitance to ground. This method of grounding the generator neutral is used where selective tripping of circuits for ground faults is not required. In some existing plants the older installation of a potential transformer between each generator neutral and ground has been replaced with a distribution transformer with secondary resistor. All new power plants of the unit system will have this method of neutral grounding, which gives less transient overvoltage than an isolated neutral or potential transformer. With either method, the detection of a ground by means of a voltage relay is the same, and the current at the fault is of the same order of magnitude, much too small for the operation of differential relays. Originally, in many of the power plants, the ground detector relays gave only an alarm but lately have been reconnected to trip the circuit breaker and shut down the unit the same as for a differential relay operation. The ground detector relay is usually of the induction type set to pick up for grounds down to 10 per cent of the generator winding at the neutral end. Tripping the unit off, instead of giving alarm only, permits using a sensitive relay without need for protecting the relay against a continuous overvoltage. Although Figures 1, 2, and 3 show the unit system of a transformer bank for each generator unit, actually the Bureau has many power plants where two or more generators are connected to a single transformer bank. Sometimes these generator busses have circuits connected to them for serving local communities or station service. In power plants having generator-voltage busses where selective tripping is required for ground faults, the generator neutrals are grounded through neutral circuit breakers and reactors which limit fault current in generator windings to a value slightly less than a 3-phase fault current.

Transmission Line Protection

The 3-zone type of distance relay is used for protection against multiphase faults on nearly all transmission lines of 115 kv and higher voltage and also on lines of lower voltage where there is insufficient difference between maximum load current and minimum fault current to permit the use of overcurrent relays. Both the conventional distance relays and long-line type of distance relays having phase-angle discrimination are used as required. As a general rule, the conventional type is preferred because of the faster speed of operation wherever the long-lines type minimum ohms would require a current transformer ratio that was higher than required by load current. On 115-kv lines, it has been calculated that line lengths usually must be in excess of 100 miles before the long-lines type distance relay should be considered.

Figure 3. Use of wound-type current transformers in line circuits

Figure 4. Use of wound-type current transformers in transfer bus position

Carrier-current pilot relaying with terminal circuit breaker arranged for reclosing in 20 cycles is usually applied to all transmission lines rated 115 kv or greater. Distance-type carrier relaying is usually more applicable on our systems than the current phase-comparison type since fault currents are in general too small for a good application of the latter. The simplicity of the current phase-comparison relaying scheme has certain advantages and an attempt to apply it to Bureau systems is made wherever possible. However, so far we have found only one 80-mile 230-kv line sections where carrier relaying and fast reclosing circuit breakers were required and where the fault currents were high enough to allow the application of current phase-comparison relays. Other 230-kv lines on this system will have distance-type carrier. The backup relays on the line with phase-comparison relays will be distance relays and product-type induction-disk ground relays. It is expected that experience with this line will indicate whether current phase-comparison relays will have greater application on Bureau lines in the future.

Some of the special relay characteristics required for long high-voltage lines were described in a previous paper.[1] The high frequency residual current transient that is likely to occur when a long transmission line is energized is of sufficient magnitude and duration to cause undesirable operation of carrier-current ground relays. However, a transient shunt has been developed which allows only 60-cycle current to enter the ground fault relay, and this has obviated this difficulty without increasing the relay operating time.

The Bureau's practice has been to install capacitor potential devices for relaying instead of potential transformers wherever there is a saving in initial cost, except where potential transformers are required for revenue metering. Capacitor potential devices have a cost advantage at 115 kv and higher voltages, and also at 69 kv if coupling capacitors are to be furnished for carrier-current purposes. The problem of adjusting the devices has been solved by use of apparatus for compensating for the reactance drop in power transformers under load conditions and comparing the output of the capacitor potential device with the compensated voltage from a low-side potential transformer.[2] Where it is convenient to unload the power transformers, reactance drop compensation is unnecessary.

Bus potential is preferred for the restraint for distance relays and is provided for this purpose at substations having a single main bus. In double-bus arrangements where either bus may be de-energized while the other bus serves the transmission lines through the same sets of protective relays, it is believed that line potential is preferable to the complications of switching between bus potentials. With automatic reclosing circuit breakers, the use of line potential may result in failure to trip or in slow tripping after reclosing on a close-in permanent fault. Mechanical interlocks are provided between line disconnecting switches and line grounding switches to prevent operating errors from causing faults. Al-

though standard distance relay elements are sensitive to small values of potential so that probability of failure to trip because of insufficient potential is quite small, there has been some concern over the omission of backup protection in view of the possibility of solid faults close to the substation. It has been claimed by some that the extreme sensitivity of distance relays has disadvantages in that the relays may trip falsely on transients introduced by capacitor potential devices; however, the Bureau has had no direct experience of false tripping from this cause.

The Bureau has been operating three separate 115-kv systems protected by ground-fault neutralizers without overhead ground wires. However, on two of these systems the transformer neutrals now are being changed to a solidly grounded connection, and the ground-fault neutralizer coils will be salvaged. At the same time, overhead ground wires are being installed on the 115-kv transmission lines; and on some of the line sections carrier-relaying and 20-cycle reclosing circuit breakers are being added. The ground-fault neutralizers have been effective in clearing about 80 per cent of the total number of faults on the 115-kv lines so protected, leaving about six faults per 100 miles per year to be cleared by relay action. On 161-kv lines with overhead ground wires for which records are available, the number of faults has averaged about 0.5 per 100 miles per year.

The tapping of 115-kv and lower voltage lines is common practice with the Bureau since in most such cases there is only one long line traversing the area. Tapping that line is the only economically feasible method of serving loads at intermediate points, and transmission lines of this voltage sometimes serve as "Distribution" lines. The current phase-comparison type of carrier relaying cannot be readily applied to tapped lines because an extremely high minimum pickup current is required. It is considered essential that all types of faults should be protected against, including 3-phase faults at the end of long lines.

Tapping of transmission lines gives rise to a number of relaying problems with regard to reclosing terminal circuit breakers in 20 cycles, especially where the circuit fed from the tap has an appreciable amount of connected synchronous machine capacity, either small local generators or irrigation pump motors. Available data indicate that a current as small as 5 amperes fed to the fault on the 115-kv line from a tap on the line may delay the deionization sufficiently to prevent successful reclosure. Relaying with primary currents of this magnitude would be difficult where normal load current is several times as great. One possibility is that of using undervoltage relays at the tap substation, but for completely reliable relaying such a scheme would require transmitting a continuous carrier-blocking signal from one of the main terminals. Besides the disadvantage of not being able to use the carrier channel for other purposes, there would be complications in preventing false tripping in the event that carrier failed.

Figure 5. Arrangements at small substations

Studies indicate that sequential tripping is the fastest that can be obtained with current actuated relays for most lines tapped with synchronous machinery loads, and reclosing times in excess of 20 cycles must be accepted in these cases.

Transmission lines that are merely feeders to isolated loads are not furnished with carrier relaying. Such lines usually have circuit breakers arranged for automatically reclosing three times. Where the line may be energized from the load, undervoltage relays energized from line potential are provided to assure that the line is de-energized before reclosing.

Ground relays of the distance type are being considered for circuits which require fast clearing of all faults but which for some reason do not permit use of carrier relaying. One example is a transmission line including a section of high voltage cable in which the attenuation is too great for a good application of a carrier-current relaying channel. Distance ground relays may also be advantageous where one of the line terminals at times has an ungrounded neutral, but for this application the relays must be of a type that is actuated by the total current in the faulted phase rather than the zero-sequence component.

Line protection is provided at a station which does not have high-voltage circuit breakers by means of low-voltage current transformers and capacitor potential devices connected to the high-voltage side of the transformers. This arrangement is preferred because it allows a greater percentage of the line to be protected by first zone of the distance relays, while still protecting the transformer bank at the station. If the power transformers have load ratio control or equivalent, the effective current transformer ratio is a variable and must be given special consideration in setting the relays.

The Bureau has applied transformer impedance drop compensators for adapting low-voltage potential sources to distance relaying of transmission lines. In accordance with the manufacturer's recommendation, the compensators are adjusted to compensate for only 90 per cent of the voltage drop in the power transformers, in order to assure against overcompensation which would cause incorrect directional element operation for close-in faults. In calculating the relay settings, a correction is made for the error in the compensator caused by the potential circuit burden of the relays. Since the compensators are no more accurate than the distance relays themselves, we have found that there is nothing gained in using compensators where the power transformer carries the total fault current, for it is just as effective to omit the compensators and include the transformer impedance as part of the impedance of the protected line section. Where the transformers carry a variable major fraction of the fault current fed from the station, a first-zone setting based on the calculated minimum value of this fraction has proved satisfactory without resorting to transformer drop compensators.

In some installations where relay coordination is quite simple, three zone elements of distance relays are available for protection of the line itself without need of providing backup protection against faults in adjacent sections, and settings have been used which assist in the location of the fault by means of relay target indication. Though this method of setting the relays gives an unnecessarily short reach to the first-zone element, the second- and third-zone time settings can be quite fast.

Induction-disk relays operated from the residual line current are provided on all lines of solidly grounded neutral systems for protection against ground faults. These relays are directional if this feature

is required, usually polarized by transformer neutral current. Either the product-type or directional overcurrent-type of directional ground relay is used, depending on which best suits the station design. Where the line current transformers are low-ratio bushing type, the lower burden of the product-type ground relay is preferred. However, at the larger power plants it has been found that the large number of product-type ground relays has placed an excessive burden on neutral current transformers, and the directional overcurrent type would be preferred. It has been calculated that co-ordination can be obtained with either type of relay, but the product type is more difficult for the man in the field to calculate.

Substation Protection

The arrangement of the substations varies with the size and importance of the loads, and the number of high-voltage circuits terminating there. Thus, the arrangements shown in Figures 1, 2, and 3 for power plant switchyards also apply to the larger receiving substation switchyards. However, Figure 5 shows seven arrangements that are more generally used for load substations of about 30,000 kva or less in capacity.

In Figure 5(A) and 5(B), the transformer differential relays trip all of the circuit breakers for either transformer or bus faults. It is believed that the omission of the transformer circuit breaker on the high-voltage side is justified in most cases by the infrequency of transformer faults. No spare circuit breaker is provided, since a line circuit breaker can be removed for maintenance after a by-pass switch is closed between lines. This type of by-pass is preferred to a by-pass switch between bus and line, since transformer differential protection can be retained and the two transmission lines can be relayed as a 3-terminal line. Figure 5(C) shows a method frequently proposed as an alternative to 5(B) for an unimportant load served from an important transmission line. Reliable transformer protection is still furnished while saving one high-voltage circuit breaker, but the line must be relayed as a 3-terminal line. However, if the transformer capacity is relatively small without a grounded high-side neutral and if the load feeds back no fault current to line faults, this substation can be practically ignored in setting the line relays at remote terminals, and no line relays need be provided at this substation. The arrangement in Figure 5(D) has been used quite extensively. It is the same as 5(C) except that fuses have been substituted for differential protection to save the cost of the high-voltage circuit breaker. There has been some opposition to high-voltage fuses by operating men because of unexplained operations and because operation of one fuse causes the transformer bank to operate single-phase with possible damage to synchronous machinery loads. Phase-balance relays can be applied to trip the low-side circuit breaker if a fuse blows for any reason, and thus would prevent damage to machines. These relays would detect an unbalance in current or voltage or both, depending on the characteristics of the connected loads. The elimination of all transformer protection at the substation as shown in Figure 5(E) seldom is used except on radial lines terminating in transformers. Distance relays at the source terminal must be set to reach low-voltage faults at all load substations, and good protection and relay co-ordination are possible if the reach is approximately the same to low-voltage 3-phase faults at all substations. A carrier-current transferred-tripping scheme for transformer protection could be used with the arrangement shown in Figure 5(E), but our experience with this type of protection has not been good as it has been found difficult to prevent false tripping. Figure 5(F) has been applied when it is desired to force operation of line relays at the terminals. Here a spring-operated grounding switch protects the transformer against internal faults by means of differential relays and also protects the transformer against overheating as a result of carrying sustained ground-fault current to line

Figure 6. Loss of relay reach for line-to-line faults on far side of delta-Y transformer bank as compared to 3-phase faults upon which calculations are usually based

faults when the neutral is grounded. The neutral current relay must have sufficient time delay to allow the normal operation of remote relays to clear the fault. The grounding switch protects the transformer adequately, but has the disadvantage of causing an interruption to service on the line. Figure 5(G) makes use of a 3-phase interrupter disconnecting switch for removing the transformer from the lines where the fault duty is 500,000 kva or less. The interrupter is new and the Bureau does not have any in service as yet. Its cost is less than that of a circuit breaker and it has operating advantages over fuses by being 3-phase in operation, and over grounding switches because it would not disrupt service on the transmission line. Its use appears promising where the interrupting duty is low enough to allow its application.

The high-voltage switching at these substations influences the choice of whether or not to ground the high-voltage neutral of the substation transformers. In Figures 5(A) and (B) with a Y-connected high-voltage winding, grounding the transformer neutral is definitely desirable, since relaying of faults on the transmission line would be improved. In 5(C), (D), (E), (F), and (G), the opposite is true from a relaying viewpoint even though common practice is to ground the neutral in order to save the cost of increased transformer insulation. Figure 5(D) is particularly objectionable and is never used in protecting a transformer having a grounded high-voltage neutral. We have one transformer installation at a line tap where the neutral of the Y-connected high-voltage winding is ungrounded in order to permit use of fuses and, by increasing ground fault current at the main terminals, to improve the carrier relaying required for simultaneous tripping and 20-cycle reclosing of circuit breakers. With a grounded neutral at the tap, the arrangement shown in Figure 5(C) is generally used and the transformer circuit breaker is arranged to be reclosed immediately after tripping for a line fault. Figure 5(G) would be less objectionable than 5(F) for a grounded-neutral transformer bank, since an operation of the neutral current relay would cause an outage on the tap circuit and not on the line itself, assuming that the main terminal circuit breakers were immediately reclosed and the fault was transitory.

At the larger and more important substations that are main junction points in a high-voltage network, a circuit breaker is furnished for each circuit including transformer circuits, and the bus is protected by differentially-connected over-

current relays separate from the transformer protection. Complete reliance is placed in the differential relays. Backup protection provided by distance and residual current relays at near and remote terminals of transmission lines is incidental and, in many cases, incomplete since it is believed desirable to avoid setting high-voltage line relays to reach into low-voltage power systems connected to the substation. The relaying on these low-voltage systems is usually of the time-delay overcurrent type, making co-ordination difficult especially where the low-voltage system is owned and operated by a customer. The problem of securing complete transformer backup protection by line relays is further complicated because of the mutual impedance effect if the substation is fed fault current from more than one transmission line.

At some of the substations of line taps, calculations have shown that fuses would be slower than the primary transmission-line distance and ground relays in clearing either high-voltage or low-voltage transformer faults, and the fuses have been omitted with reliance being placed on the terminal relays. Since with delta-Y transformer connections the transformer blocks the passage of zero-sequence current, the ground relays for the transmission line will not provide any protection against low-voltage faults, and consequently such faults must be cleared by the distance relays. If the transformers are Y-delta or delta-Y connected, which gives a phase shift, the reach of the distance relays will be greater for 3-phase faults than for line-to-line faults on the low-voltage side. This is usually not appreciated by the relay engineer. As indicated by the curve in Figure 6, the difference in the reach for the two types of fault is a function of the ratio of the impedance from internal machine voltage to relay location to the impedance from the relay location to the fault. It is apparent that the second- or third-zone elements of the relays must be given a long reach in order to give complete protection against all types of transformer faults, especially if some allowance is made for impedance at the fault and for part-winding faults. Consideration also must be given to maximum load currents in order to prevent false tripping with the longer setting required to reach low-voltage line-to-line faults. Careful calculations must be made, therefore, if transformers are to be protected by the line relays at remote terminals, but the protection has been considered adequate for new transformers as a temporary expedient at substations where ultimately a high-voltage circuit breaker and differential relays will be provided.

At important unattended substations it is planned to provide automatic reclosing of line circuit breakers and to provide supervisory control of all circuit breakers and of some motor-operated disconnecting switches. Where necessary, dead-line-check voltage relays and synchronism-check relays are used with the automatic reclosing; but on feeder circuits where these check relays are not needed, the reclosing relay recloses the circuit breaker three times before locking out. Where carrier relaying and 20-cycle reclosing are provided, either the slower type reclosing or the supervisory control is usually omitted, but one of these methods is available for reclosing the circuit breaker after clearing transitory line faults when carrier relaying is out of service.

At small substations where the cost and maintenance of a battery cannot be justified, current transformer tripping is the preferred method for tripping the circuit breakers for multiphase and close-in ground faults on feeder circuits. For remote ground faults drawing current too small to operate a current trip coil, an alternating current shunt trip coil is furnished, energized from a line-to-line potential of a potential transformer or station service transformer. A line-to-line potential will not be reduced by ground faults as much as a line-to-neutral potential might be reduced. Three circuit-opening overcurrent phase relays and one circuit-closing overcurrent ground relay are furnished for each feeder. If calculations indicate that this scheme will protect against all faults in the protected section, we believe the scheme to be more reliable than capacitor tripping or 24-volt battery tripping.

At power plants the voltage of the station battery for opening and closing circuit breakers and other purposes is 125 volts or, at the larger plants, 250 volts. At main substations and any substation where carrier-current relaying equipment is installed, the battery voltage is 125 volts. Batteries of lower voltage are used at small substations, especially ones of the package type.

At interconnections with smaller power systems, various relay schemes have been applied to open the circuit breaker at the interconnection during abnormal conditions of voltage or frequency. The relaying is usually designed to favor the smaller of the two interconnected systems because it is undesirable for small generators to attempt to supply the loads or charging current on the long high-voltage lines. Automatic tripping of the circuit-breaker is desirable only if there is high voltage or an excessively low frequency accompanying a reversal of power to the smaller system. Simultaneous pickup of a reverse power relay and an underfrequency relay is a definite indication that opening the interconnection would improve the frequency on the smaller receiving system. The Bureau has used instantaneous overvoltage relays to protect generators on the small power systems against becoming self-excited while charging the high voltage transmission line. Where a sudden overvoltage can result without reversal of power flow or increase in frequency, there is usually no need for interlocking with other relays. Overvoltage relays, which are used for protection against overvoltage resulting from overspeeding of hydroelectric generators when a major part of the load is suddenly dropped, must have frequency compensation.

Conclusions

1. Economies in switching arrangement at power plants and receiving substations may be made by omitting unnecessary high-voltage circuit breakers and taking advantage of the infrequency of transformer and high-voltage bus faults.

2. Transfer of line protection to the spare circuit breaker may be accomplished automatically without transferring current transformer circuits with possible false tripping.

3. Equipment may be adequately protected against all types of faults with a minimum of circuit breakers and relays and give adequate service reliability and dependability.

Discussion

Eric T. B. Gross (Illinois Institute of Technology, Chicago, Ill.): This paper is a valuable contribution to the art of protective relaying since it describes the practices used in a number of large systems at various voltages and because simplicity seems to be one of the guiding principles in the selection of appropriate protective schemes.

I am wondering if "gas and pressure protection" has been considered for relatively small transformers where differential protection is far too expensive. Gas-alarm relays are also helpful to supplement differen-

tial protection of large transformers since they are much more sensitive than any other type of transformer protection.[1] This question seems particularly timely since I happen to know of some recent transformer breakdowns which were due to core faults, for example, where failure of insulation between laminations was responsible. This is a type of unbalance which is too small for detection by differential relays. Turn-to-turn faults, which are sometimes the beginning of winding failures, are a similar unbalance.

Since the ground fault neutralizers in the 115-kv systems seem to have given satisfactory service, it should be of interest to learn if together with the grounding other changes of some of these systems are also contemplated.

It is noted that ground distance relaying is being considered for circuits which do not permit carrier relaying. This type of distance relaying deserves much wider application than it has had in the past.

The use of capacitor potential devices on bus bars is an interesting application of such equipment. It would be helpful if the authors would comment in more detail on their experiences with potential devices in general, and on the advantages of this arrangement.

W. A. Morgan and R. W. World: We appreciate the comments of Professor Eric T. B. Gross, as he has touched upon parts of the paper that should receive further discussion.

Gas and pressure protection would be given greater consideration if it were made available for sealed-tank transformers. We have one gas accumulation relay in service on a 3,000-kva conservator-type transformer, to give an alarm only. The relay was added after a core fault occurred. We are looking forward to the further development of these relays in this country, but because of the impressive record of transformers as regards faults we have not actively encouraged their development. It is difficult to understand the reluctance of manufacturers to promote the gas relays, in view of their excellent performance record in Canada and Europe.

Ground fault neutralizers are being removed from service because the systems are expanding and are becoming networks consisting of many hundreds of miles with one or more loops which would require many coils. The existing coils are of the 10-minute rating type with automatic by-pass switches. On two systems, they will be replaced by overhead ground wires and solidly grounded transformers sometime this year.

On one system, they will be retained as long as possible because this sytem will be free of interconnections to solidly grounded systems for several years and the cost of adding the overhead ground wires can not be met at this time. Overhead ground wires and 20-cycle reclosing circuit breakers will eliminate the need for the ground fault neutralizers, which will be modified and relocated on systems of lower voltage.

Capacitor potential devices are furnished in place of potential transformers on busses where burden permits. It is found that one 3-phase bank of potential devices rated 150 watts per phase can carry the burden of the instruments and relays of at least three transmission lines. Contrary to previous thinking it has been found that potential device performance is improved when the devices are loaded to near their rating. It is believed that some users of capacitor potential devices may have blamed the devices for incorrect relaying where line potential is used and where automatic circuit breaker reclosing is applied. However, it is believed that present-day analysis shows that the relays themselves are likely not to operate correctly when the circuit breaker recloses on a permanent fault and line potential is used, whether this potential is supplied by potential transformers or capacitor potential devices.

Desert Measurements of Corona Loss on Conductors for Operation Above 230 Kv

Synopsis: This paper reports corona loss measurements made under desert conditions on 1.25-inch and 1.4-inch type-HH copper conductor and 1.4-inch conductor. The variations from wattmeter equipment are discussed. Conditions and losses measured indicate that factors, yet unknown, exist in some desert areas that cause corona loss values to occur at considerably lower voltages than would have been anticipated from previous tests in coastal climates. The tests indicate the necessity for use of added liberality in selecting conductor diameter or confirmation by extended field tests of the existence or absence of the phenomena described. The 1.4-inch type-HH conductor showed adequate liberality for desert operation. The 1.4-inch stranded cable, though adequate in coastal or under normal climatic conditions, showed losses which might prove uneconomical under conditions encountered in the desert areas. The 1.25-type-HH cable appeared definitely inadequate for use in desert areas.

IN 1938 the operation of the 287-kv Boulder Dam transmission lines of the Department of Water and Power up to that date was recorded before the Institute.[1] It was reported that studies then were in progress in the desert area in the vicinity of Victorville measuring corona loss on 1.25-inch and 1.4-inch type-HH cable and on 1.4-inch steel-reinforced aluminum cable. These studies essentially were for basic information in connection with the design of the third circuit from Hoover Dam to Los Angeles.

The present interest in transmission at higher voltages in other parts of the United States and Europe, and the feasibility of going beyond 220 kv for high-load interconnecting circuits, prompts the presentation of this information for such value as it may be in the design of lines for these higher voltages.

Purpose

From studies which have been conducted at Stanford University[2,3] and subsequent theoretical analysis,[4] it was indicated that 1.4-inch diameter conductor would operate satisfactorily at 287 kv and that the segmental-type cable carried some liberality above the diameter necessary for operation at 287 kv. This diameter initially had been established as a result of studies conducted primarily on stranded-type cables so that at the time specifications were issued for conductor on the first two Boulder transmission lines there were not sufficient data to permit establishing a differential in diameter between segmental- and stranded-type cables.

Results of tests later conducted at Stanford[5] indicated that the 1.25-inch diameter cable might operate satisfactorily at 287 kv with resultant reduction in capital investment in both conductor and towers. Contrary to this, however, observations on the desert in the vicinity of Victorville had indicated that under certain climatic conditions not involving storms, corona was visible on 1.4-inch diameter conductors in amounts appreciably more than would have been expected from the measured loss values or visual observations made at Stanford. Victorville is located at the base of a gradual slope on the northeastern side of the Sierra Madres at an elevation of approximately 2,800 feet. These phenomena of unusual corona loss were not observed generally in the desert and did not exist at elevations between 3,000 and 4,000 feet. Little value would have been gained by testing 1.25-inch diameter conductor at the Ryan High Voltage Laboratory since there had been interjected the question of desert surroundings as an item affecting corona loss. It was of utmost importance, therefore, that tests be made on the desert, and in so far as possible in the vicinity where the unusual corona conditions had been observed.

The fundamental purposes of the tests, therefore, were to determine: first, whether or not 1.25-inch diameter segmental cable could be utilized satisfactorily at 287 kv; second, the relation of diameter between stranded- and segmental-type cable for the same corona loss levels; and third, to determine the exact losses which were existing under the desert conditions upon 1.4-inch HH and other conductors and, if possible, the cause for the apparent increase in corona loss above that observed under atmospheric conditions at Ryan Laboratory.

Test Location

It was highly desirable that any test location established be adjacent to one of the two switching stations, either Victorville or Silver Lake, in order that the connection might be made to a switch rack rather than tying into the transmission lines at a regular tower structure. The decision to utilize Victorville was determined for several basic reasons. The voltage rise which would be available at Victorville, 183 transmission-line miles from the generator end, was such that with slight overvoltages on the generators at Boulder it was possible to develop 365 kv for test purposes at Victorville. It was decided early to use the water-column

Figure 1. Suspension and dead-end structures for supporting test spans

Figure 2. Arrangement of wattmeter multipliers and test connections

resistor-type wattmeter multiplier as used for the previous laboratory tests.[3,5] It was found that water available from a well at Victorville had a specific resistance approaching 3,000 ohms per centimeter cubed which was suitable for use in such water resistors, while the water at Silver Lake carried a high chemical content and very low resistance which would have required the use of distilled water had that location been selected. The fact that the unusual corona conditions had been observed only 14 miles to the east of Victorville and the proximity of Victorville to Los Angeles, allowing for easy transportation of material and test crews, coupled with the other factors mentioned, established this as the location for test. A section of right-of-way extending westerly from the switching station, which was eventually to be utilized for the third circuit from Hoover Dam to Los Angeles, was available upon which to erect the test line.

Physical Arrangement

Victorville switching station is the second sectionalizing station between Hoover Power Plant and Los Angeles and is located adjacent to a transcontinental highway. The station structure from which takeoff could be most readily accomplished terminated a portion of the buss tying directly to the section of transmission line extending between Victorville and Silver Lake Station to the East. A single span carried across the State highway to the start of the test line was the only construction necessary in addition to that required for the test specimens. The test line thus electrically became a portion of the line between Victorville and Silver Lake so that under any fault conditions it would be relayed as a portion of that section of line. Under normal test conditions it was the Victorville end of such line with no switching at Victorville. To provide for emergency de-energizing, switching was accomplished over the carrier current relay circuit to Silver Lake. This switching though provided was never required during the test, normal switching being carried out by the regular supervisory control from Hoover Power Plant.

Four spans were provided for the erection of test conductors, the first two totaling 800 feet and the second two totaling 700 feet. These dimensions were selected because of irregularities in the terrain and in order to provide as nearly as possible similar ground clearance in all of the test spans and to accommodate the specimens available. The structures were of wood poles with latticed steel channel cross-arms and with guy supports to the tops of the poles to form an H-frame structure. Conductor spacing was $32^1/_2$ feet horizontally on a 65-foot cross-arm identical with the Boulder lines. Ground wires, rather than being spaced 50 feet as on the Boulder line construction, were carried on the top of the poles at a separation of $32^1/_2$ feet but at elevations of 30 feet above the conductor, to this extent duplicating the Boulder construction. Suspension and dead-end structures as they appeared during stringing operations are shown in Figure 1. The slight variation in ground-wire spacing from that existing on the Boulder transmission circuits was determined to produce negligible change upon the voltage gradient at the conductor surface, and therefore the difficulty of providing identical spacing was considered unjustified.

For the initial tests the two spans adjacent to the metering connection carried 800-foot specimens of 1.25-inch type-HH cable and the next two spans carried the 700-foot specimens of the 1.4-inch steel-reinforced aluminum cable conductor. Jumper loops between the two specimens were provided for quick removal so that the combined losses from the two samples could be measured followed promptly by the measurement of the losses from the specimen adjacent to the meters. The loss from the more remote specimen could then be determined by subtraction.

Metering

For metering the losses at this location the fundamental circuit used was that described for measuring corona loss at the Ryan High Voltage Laboratory, Stanford University.[2,3]

The scheme essentially uses a water resistor as a high-voltage multiplier for the voltage circuit of the standard low-power factor wattmeter. The actual current into the conductor under test is carried through the current coils of this meter. Particular care is taken that all leads and the meters themselves are shielded to the point where losses are intended to be measured. Unlike the laboratory tests, this circuit used a fixed size of water resistor with resistance varying slightly with current and resultant temperature rather than maintaining constant current through the resistor as was the practice at the Ryan Laboratory. It was necessary at Victorville, therefore, to measure the resistance of the water entering the water column, the current actually flowing in the water column, and the water temperature in order to deter-

mine the heat being generated, the temperature rise, and the resultant total resistance of the column at the time each measurement was taken.

The general arrangement of equipment is shown in Figure 2. The down-leads at the center of the jumper loop and connecting tubes over to the wattmeter assembly under the platform carry shielded leads from the wattmeters located on top of the water resistor shield to the dead-end string, the first point where corona loss is measured. Observers during test runs were stationed on the platform above each wattmeter assembly, reading through telescopes the wattmeters and milliammeters showing conductor current. Figure 3 shows a single water column assembly. The shield at the top of the water column was approximately six feet in diameter with the outer edges composed of 2-inch iron pipe. Additional rings or loops were provided extending beyond the insulator supports. This large metal surface at the top with the capacitance of the insulator stacks provides a relatively uniform field along the water column hanging vertically from the center of the shield. The water resistors were made of capillary tubing approximately 1/8 inch in diameter. The water flow through this tubing was at the rate of from 15 to 20 gallons per minute and the maximum current somewhat below 50 milliamperes. For the voltages involved the energy dissipated in this column was at the rate of between 10 and 12 kw. Wattmeters were located in screen shielding cages on top of the shielding members. In addition to the wattmeter and charging current readings, the current through the water resistors, approximate line voltage from coupling capacitors, resistance and temperature of water entering the water column, generator voltage at Boulder received by telephone, wet and dry bulb temperatures for humidity, barometric pressure, and noise measurements were recorded with each reading loss. The water-flow quantity and the normal resistance of the water in each of the water columns was measured between each test. The relation of the meters and measuring and shielding equipment is pictured in the circuit schematic diagram of Figure 4. Although voltage indication was available from coupling capacitors, its accuracy was not considered sufficient for these tests. The line voltage was actually determined from the computed resistance of the water column and the measured milliampere current through that column. Three of these measurements were available providing considerable check upon errors in meter reading.

Metering Accuracy

Wattmeters

The wattmeters used for these tests were the same meters previously used at the Ryan High Voltage Laboratory. Calibration of these meters was checked after their transportation to Los Angeles by several methods and by comparison with calibrated standards. Insignificant changes had occurred from the corrections previously applied so that values as actually read by scale divisions would correspond identically with those as determined under the Stanford conditions. Two sets of meters were necessary because of the two lengths of cable involved. The meters being read through telescopes practically eliminated any error due to parallax. Reading was attempted to 0.1 of a division. Estimate was probably within 0.1 of a division of the actual deflection. With some meter swing at the time of reading, the average readings probably were within 0.2 division of the actual value. This would correspond to 14 watts and 32 watts per phase respectively on the low- and high-range meters being used.

Shunting Capacities

Any capacities shunting the meter coils could affect the accuracy of the reading. The shielded lead, carried approximately 50 feet from the dead-end insulator string through copper cable or copper tubing back to the meter, has capacitance to this tubing which is, in effect, shunting the current coil of the meter. A study made to determine the possible magnitude of this error showed that the maximum voltage across the coil was approximately 3.37 volts for 60-cycle frequency, which would produce a theoretical error reading of only 0.01 division. Although harmonic voltages would produce error readings in proportion to their frequency, their existence is in relatively smaller magnitude. Computations indicated that even at higher frequencies this error of 0.01 to 0.02 of a division probably would not be exceeded. Tests have been made at Stanford[3] with balancing impedance and a shielded lead circuit such that the voltage drop through this shunting impedance

would have the same percentage and phase angle as the voltage drop through the current coils of the meter. With between 80 and 100 feet of shielded lead between the meters and the loss specimen, the balancing impedance could be cut in or out of the circuit with no visible movement of the meter needle. These checks and other computations indicated that shunting capacities were not producing measurable errors in either the Stanford or the Victorville tests.

Voltage Measurements

Since variation in burden on coupling capacitors and saturation effects of iron components at the overvoltages involved made it questionable to rely upon this source for voltage measurement, voltage was determined at the test site by milliammeter readings of current and corresponding resistance of the main wattmeter resistors. Temperature of the water entering the base of each column was read with each two or three voltage readings. Coming from a large source there was little fluctuation in the temperature. Readings were taken to the nearest 1/2 degree. Water flow was measured before and after each group of readings, but since regulated pressure was maintained, the flow also showed little variation. Since water has a finite temperature resistance characteristic, the resistance of the water column varied materially with the voltage and consequent current and heating of the water. Current readings were made for each of the multipliers for each voltage applied. The error in these readings again was probably not over 0.2 milliampere, but since the normal reading was as low as 20 milliamperes, the error could thus be one per cent, or the equivalent of approximately three kv. Since three meters were read and compared, these errors probably averaged less than the above amount.

The formula derived for the computation of the resistance of the water column from resistance, temperature, and current readings was as follows

From studies of literature and measurements of the actual water being used, the formula, $R_{50} = [(20 + T)/40]R_t$, was confirmed. By plotting the resistance values thus computed as a function of current, it was possible to establish a smooth curve relation, correct error readings, and be assured of a much higher accuracy than that for any single reading. It is believed that voltage determinations were within one per cent accuracy.

Results of Tests

Type-HH 1.25-Inch Cable

Tests on the 1.25-inch type-HH cable were conducted on four days extending over a period of nearly twelve weeks—September 26, October 17, October 24, and December 19. With the possible exception of December 19, the data for the several runs on individual days correlated so closely that a single curve can be plotted for each day and be truly representative of the entire group of data. Typical curves for these data are presented in Figure 5. Temperature corrections were made only where the cable temperature was greater than 102 degrees Fahrenheit by the first power relation of the air density factor. Data within this range were used without correction.

The first test conducted on September 26 was on the cable as received, having been washed and rinsed exteriorly only before shipment. The loss at 287 kv was in excess of 6 kw per mile. After approximately four weeks of weathering, the test conducted on October 17 showed very little change in the loss, being only slightly lower in the lower region and a fraction higher in the region above 300 kv. At this time it was evident that the excess dye grease or lubricant carried on the inside of the cable was beginning to seep through the joints between the segments. Dust was collecting at these locations and it was indicated that any reduction in loss resulting from weathering was being counteracted by these dust deposits and by small dust precipitation areas. These dust precipitation areas were novel to the authors, were generally elliptical in shape, and occurred both on segmental- and stranded-type cables. They were determined to be deposits of dust, the result of precipitator action in the immediate vicinity of a corona brush, estab-

Line curves represent approximate extreme variations.

lished either by a rough spot or some contamination on the surface of the cable. These were also observed on the Boulderline conductors, but after several years of weathering no longer exist.

The 1.25-inch cable was lowered, flushed internally with gasoline and given the external gasoline, soap, and water wash identical with that normally given to conductors under laboratory tests.[2,5] Since the 1.4-inch stranded cable previously had received this treatment at the Ryan High Voltage Laboratory, it was given an external wash with clear water through a ring of high-pressure jets. Immediately following the washing treatment, October 24, the 1.25-inch cable, though indicating a slight reduction in loss in the lower loss range, had an increased loss of approximately 1 kw per mile at 287 kv, or a shift along the voltage axis of approximately 10 kv. In the upper range or high-loss range of the curve, the shift approached ten kv; that is, the same loss occurred at ten kv lower voltage than before.

Final test on this cable was conducted on December 19, two months later. At this time the loss had reduced somewhat, indicating slightly less than six kw per mile at 287 kv for 100 degrees Fahrenheit cable temperature, but in carrying into the higher voltage range the loss was still somewhat above that determined under the initial erection conditions of the cable. For comparison a curve also is shown extrapolated from tests on 1.4-inch and 1.65-inch type-HH cable conducted at Stanford University which would indicate that for that location the corona loss on 1.25-inch type-HH cable at normal operating voltage of 287 kv would be less than one kw per mile. This change in loss is equivalent to a shift in voltage of over 50 kv in the lower loss range, while in the upper range of the curve a voltage shift of nearly 70 kv is necessary to produce the same loss. The particular significance of these tests is that by comparison with tests at the Ryan High Voltage Laboratory some unknown factors are present in this area of the desert which cause corona to start at a voltage of 50 to 70 kv below that at which it is experienced on corresponding conductors at the Ryan Laboratory.

In addition, contrary to the experience at the Laboratory, the internal and exterior washing of the cable did not produce the normal reduction in loss previously experienced. The loss figures remained almost identical with those of the initial test actually showing a slight increase immediately following washing and then with weathering dropping somewhat below the losses experienced under initial test conditions.

Figure 9. Summary of corona-loss data on 1.25- and 1.4-inch type-HH and 1.4-inch steel-reinforced aluminum cable—Victorville and Stanford Tests

Victorville Tests: 1.25-inch HH and 1.4-inch steel-reinforced aluminum cable weathered two months after washing—1.4-inch HH weathered 16 months after washing

Stanford Tests: 1.4-inch HH 15 days after washing—1.25-inch HH extrapolated from above and similar tests on 1.65-inch type-HH cable—1.4-inch steel-reinforced aluminum cable 16 days after washing

Tests on 1.4-Inch Steel-Reinforced Aluminum Cable

Tests conducted on 1.4-inch steel-reinforced aluminum cable are shown in Figure 6 and cover the identical dates mentioned for the previous conductor tests. The loss on this cable was determined of necessity by making a combined loss measurement on the two sections, including the 800 feet of 1.25-inch cable and the 700 feet of 1.4-inch steel-reinforced aluminum cable conductor and then subtracting the loss computed for the former from the combined loss measurement. Since temperature variations were usually very slight between consecutive runs and since the loss values as determined for the 1.25-inch cable showed little variation between runs on the same day, it was possible to use the loss values for the run immediately preceding or immediately following the combination run and thus be assured of a high degree of accuracy. It is of interest to note that the two runs on September 26 showed somewhat different results in the higher loss regions. The loss at normal operating voltage, 287 kv, for these two tests was between 2.5 and 4 kw per mile, corresponding to a voltage shift between the two tests of approximately 20 kv, while in the region approaching 10 kw per mile the curves showed a voltage separation of nearly 35 kv for the same loss. Tests conducted four weeks later on October 17 showed very little difference between consecutive runs and the loss values were approximately midway between the two tests of September 26.

Following the test of October 17, the conductor was given an external rinse with a circle of high-pressure water jets carried along the cable on a small trolley. Whether or not a surface condition had developed as a result of the treatment and storage at Stanford University, which was removed as a result of this washing, or whether dust accumulation in the desert during the short period of testing and after washing had modified the surface condition, is not known. Immediately following this washing treatment on October 24, four test runs were taken. All of these runs fell within close limits, as indicated by the curves, but showed a very material increase in the loss over the earlier tests. The loss at 287 kv was now in the vicinity of six kw per mile, corresponding to a voltage shift from the earlier tests of approximately 50 kw and very near that of the 1.25-inch HH cable. The two groups of runs taken on this date were less than ten kv apart in the upper range and approaching 5-kw separation in the range of 287 kv and below.

Tests conducted on December 19 again were quite consistent, showing approximately a 5-kv separation between various groups of runs throughout the major portion of the curve. This period of weathering of approximately two months reduced the loss in the lower range to values practically identical with those experienced at the time the cable was erected but showed losses in the higher voltage range appreciably greater than those originally experienced. The voltage shift for equal loss in the 287-kv region was from 10 to 20 kv (2–4 kw per mile) while in the 10-kw-per-mile area the shift was between 40 and 60 kv, the curves rising very abruptly for values above 287 kv. An additional curve from Stanford tests of July 20, 1933, on the identical cable is also plotted. This shows that for the stable condition of December 19, 1937, the identical cable would show the same corona loss under desert conditions at between 50 and 60 kv lower than that required in the Stanford area.

The last test on these two conductors, made on December 19, 1937, showed a moderate range of temperature from a starting temperature of 46 degrees on the cable, 36 degrees air temperature through a maximum of 72 degrees on the cable, 61 degrees air temperature, and concluding with 63-degree cable temperature and 60.2-degree air temperature. A curve sheet, Figure 7, has been plotted covering these data correcting all to the approximate maximum value of temperature recorded, namely 70 degrees on the cable. No correction was made for tests 5 and 6 or 7 and 8 which are within two degrees of the correction temperature. Curves of Figure 7 are corrected using the first power of the air-density correction factor. Although data from Stanford tests indicated the use of 2/3 power as a more accurate correction for conditions at that location, it was considered that the other factors being introduced on the desert would not justify this refinement.

Tests on 1.4-Inch Type-HH Cable

Immediately following the tests on the 1.25-inch type-HH cable and 1.4-inch steel-reinforced aluminum cable, these cables were removed and replaced by three 800-foot sections of 1.4-inch type-HH cable as used on the Boulder circuits. This cable had been given external wash with gasoline, soap, and water in order to speed the aging process and yet be as nearly as possible like the cable as erected on the actual circuits. Since this cable had been closed with a soap solution, little difficulty was contemplated from internal greases exuding between the segments. Two groups of tests were performed—the first on January 23, 1938, the final group on May 14, 1939, following 16 months of weathering. Figure 8 covers the data secured from these two tests. Curves have been drawn indicating the approximate extreme limits of these data for each test and plotted points are included showing the manner and variation between consecutive runs. All data have been corrected to 70 degrees Fahrenheit. The 16 months of weathering reduced the loss in the operating range from four kw per mile to less than one kw per mile. This was equivalent to a horizontal shifting of the curves of somewhat in excess of 30 kv.

Figure 9 summarizes the data accumulated at Victorville and includes typical curves from previous measurements at Stanford University, corrected to Victorville conditions for the 1.4-inch type-HH and steel-reinforced aluminum cable conductors, and 1.25 inch data as extrapolated. The Victorville data are plotted as areas or limits within which losses may be expected after normal weathering conditions. The advantage of the segmental-type conductor, both for desert operation as well as for conditions existing near the Ryan High Voltage Laboratory, is clearly indicated. The differential, however, is not as great under desert conditions as was previously contemplated.

Conclusions

Although tests at the Ryan Laboratory, Stanford University, had indicated by extrapolation of data from larger conductors that 1.25-inch HH or segmental-type conductor would operate satisfactorily at 287 kv, the tests here reported under desert conditions indicated that operation at this voltage was so close to the knee of the loss curve that uneconomic losses could easily result from variations in weather or atmospheric conditions, changes in altitude, or roughened surface conditions of the cable.

Tests on 1.4-inch type-HH cable, though not showing the liberality originally contemplated, indicated that operation at 287 kv was sufficiently below the knee of the curve to be within the economic loss range even for the atmospheric conditions experienced at Victorville, at higher elevations, or with possible higher voltages experienced near the generating source. These losses under Victorville conditions varied from 0.5 to 0.9 kw per mile.

Tests on 1.4-inch stranded conductor showed that losses in the normal operating range occurred under Victorville conditions at from 50 to 70 kv lower than the voltage required to produce corresponding losses at Stanford. This is approximately the same differential in voltage as was found for segmental-type cables. Likewise, it was found that corresponding losses were produced on stranded-type cable at from 20 to 25 kv below the voltage carried to produce the same loss on segmental-type cable. Again, this shift was similar to that experienced at Stanford.

Loss values found to exist under desert atmospheric conditions dictate the use of liberality in the selection of conductors to operate in such regions, or the establishment by test, prior to the selection of conductor diameter, that similar unusual atmospheric conditions are not present in the area to be traversed.

Discussion

Abe Tilles: (Pacific Gas and Electric Company, San Francisco, Calif.): This valuable and intriguing paper gives answers to some questions and raises others. It is demonstrated that the voltage corona loss curve is shifted markedly under some desert conditions. The general amount of this shift, some 60 kv, is established by careful field measurements. It is interesting that in this case "Mahomet has been brought to the mountain." To obtain the needed results the experience, techniques, and precision of measurement which have been developed over a period of two decades of corona measurements in the laboratory have been transferred "on location" to accomplish in

the field a precision measurement of a laboratory nature. The factors of safety in the original design are shown to be well chosen, and the specific problems here involved are satisfactorily bracketed to provide an engineering solution.

At the same time, of course, a general problem of very large scope is forcefully introduced. The present paper presents it but does not solve it. The basic cause of this corona increase is not established, nor is its possible extent in various other situations delimited. It is observed that variation in loss with washing and weathering is partly masked by unknown variables. In a way it is not surprising that new phenomena are being uncovered, since frontiers are being pushed forward in two directions.

For one thing, as the voltage is raised above 230 kv, even though steps are taken, such as using larger conductor radius to keep voltage gradients small in the main, possibilities of corona discharges are increased very greatly, nevertheless. For another thing, the desert is still on uncharted territory. Literally, as can be seen on the map, it is still largely uncharted; and figuratively, as attested in a great variety of lore and legend, the desert is unknown, it is different. The dryness, the large unbroken spaces, the dust and wind, the motion of large air masses, the unobstructed blaze of the sun—the desert is different. All that have been there have felt it, and they will find it interesting, but possibly not surprising, that the differences produce effects that can be measured on wattmeters and plotted on charts.

Certainly it is enough for one paper to raise clearly, as has been done, the question of corona increase in the desert; but the important questions then remain as to causes and limits of such increase, and these deserve further study.

The authors, in their paper proper, have not undertaken to speak on these further matters. It would be of great interest if, in discussion, they would care to point the way by giving such partial answers, clues, and speculations as they can on some of the questions that come to mind. How does the corona loss correlate with general atmospheric density of total ionization and with presence of ions of different sign and mobilities? How does the loss vary with day and night and intensity of sunlight, with seasonal variation in ultraviolet intensity of sunlight? How does it vary with content and variety of solid and gaseous air borne impurities? How does it vary with wind velocity and possible frictional electrification? How does it vary from place to place? Does the extra corona loss seem to be caused by varying meteorologic conditions or by local concentration of radioactive materials? Comment along these lines would certainly be of interest.

Otto Naef (American Gas and Electric Service Corporation, New York, N. Y.): We have every reason to be grateful to the authors of this paper for their decision to make known the results of these important tests, which influenced the final selection of conductors for the third circuit of the 287-kv Hoover Dam–Los Angeles line. Though carried out some ten years ago, these tests have lost nothing of their value.

An important revelation made in this paper is the statement, that after all known corrections for differences in barometric pressure and temperature were applied, the tests made at Victorville showed considerably higher corona losses than those carried out in the laboratory at Stanford on identical conductors. Apparently no explanation so far has been found of this strange phenomenon, which seems to be neither a consequence of desert climate nor altitude alone, as it was not observed in other parts of the desert, nor at higher altitudes.

Anyone who is selecting conductors for an extra high voltage transmission line may therefore be asking himself whether the projected line is likely to traverse territory where unknown climatic factors produce increased corona losses. Since field tests on a large scale are in progress at the 500-kv Test Project of the American Gas and Electric Service Corporation at Brilliant, Ohio, it was only natural for us to compare the results of our own measurements with those indicated in the paper. It was reassuring to find that our results seem to correspond to the lower values of corona loss measured at Stanford Laboratory.

A direct comparison is only possible in the case of the 1.40-inch type-*HH* conductor because all other single conductors tested at Brilliant are of larger diameter. This particular conductor was tested only single phase. After converting the measured loss into 3-phase loss and making allowance for the difference in air density factor, this conductor, when new, produced a 3-phase loss of 1 kw per mile at 347 kv, and the same loss at 386 kv after five months of aging. The sharp bend in the curve of the aged conductor begins only at 390 kv which is an 80-kv shift from the corresponding curve shown in Figure 9 of the paper for the 1.40-inch type-*HH* conductor tested at Victorville.

All the tests described in the paper were carried out in good weather, because the test installation evidently did not readily permit taking measurements under adverse weather conditions. The suitability of a conductor for operation at a specified voltage is judged, from a corona viewpoint, by the distance between the sharp upward bend in the voltage-loss curve and the point on the curve at operating voltage. At Brilliant, where the losses are recorded continuously at operating voltage, average and peak losses in all kinds of weather are readily obtained, and the suitability of a conductor is judged rather by its actual performance than by the shape of its fair-weather "Loss versus Voltage" curve.

The graphic records bring out facts that are not easily obtained by other methods. The "Stanford" curves in Figure 9, for instance, indicate that the 1.25-inch type-*HH* conductor is superior to the 1.40-inch steel-reinforced aluminum cable conductor. A similar relation was found to exist between the 1.65-inch type-*HH* and the 2.00-inch steel-reinforced aluminum cable stranded conductors at Brilliant if tested in fair weather. However, the results so far obtained from the graphic records at constant voltage, in all kinds of weather, indicate a reversal of this relation; the average loss of the 2.00-inch steel-reinforced aluminum cable conductor being smaller because it seems to be less effected by heavy rain.

The determination of corona loss on transmission lines is a complicated and difficult problem because of the many variables involved. The information presented in the authors' paper is a valuable contribution towards a better understanding of some of these problems.

Engineering Staff (Anaconda Wire and Cable Company, Hastings-on-Hudson, N. Y.): This paper reports corona-loss measurements made in the California desert some 12 to 13 years ago using the same techniques, equipment, and cables previously employed for similar tests at Stanford University. The results indicate considerably higher losses in the desert than were anticipated from the measurements near the coast. No explanation of the causes of these increased losses is suggested in the paper.

Neglecting for the moment the possibility of some unusual influence present at the desert location, three other possible causes of the difference in results suggest themselves:

Inaccuracies in Measurements

The very formidable problems in making such measurements make one look for some data regarding the accuracy of the test method. Other investigators[1,2,3] have employed several methods for the loss measurements so that possible errors could be eliminated by continuous cross-checking. Apparently, in these tests, the authors have depended only on obtaining a very approximate agreement between successive test runs under apparently similar conditions.

If additional tests had been made on short (approximately 10 feet) lengths of each conductor in a corona cylinder using the Schering bridge technique, this might have served as a direct check on the data obtained through the rather indirect and cumbersome water resistance-wattmeter method used.

It also is suggested that sphere gap sparkover measurements of desert air during the test runs may have served a useful purpose in interpreting the data.

The effect of harmonics, both generated and produced by corona, is not clearly analyzed. In the setup described, harmonic voltages can cause significant errors—these increasing with increase of line voltage. The water resistance values, too, may have errors due to the presence of harmonics.

The equation given for water resistance as a function of current, temperature, flow, and so forth, is indeterminant as written since two solutions are possible. It would be of value to restate the derivation of this equation since it is so important in obtaining the final results.

Inaccuracies in Analysis

For purposes of comparison, the curves of test data are "corrected" to some reference conditions (temperature and barometric pressure), presumably by the procedures expounded in 1937 by Carroll and Rockwell.[4] These procedures were devised empirically to agree with observed data from the Stanford tests. Possibly these procedures are not universally applicable.

In view of the rather wide variations in observed loss on a given conductor run, the method adopted for determining the losses in the 1.4-inch steel-reinforced aluminum cable is somewhat questionable. Subtract-

ing the 1.25-inch type-*HH* data from the combined losses of 1.25-inch type-*HH* and 1.4-inch steel-reinforced aluminum cable conductors can only lead to still wider variations. This is evident upon comparing Figures 5 and 6 and noting the much wider spread of curves in Figure 6. Comparing such indirectly determined losses of a round-wire conductor (steel-reinforced aluminum cable) with directly measured losses of a segmental conductor (type-*HH*) is hardly fair.

Insufficient Data

The 1.25-inch type-*HH* and 1.4-inch steel-reinforced conductors were tested over a 3-month period. During this time, four individual runs were made, representing as-received and washed conditions. Natural aging processes were therefore interfered with considerably. On the other hand, the 1.4-inch type-*HH* conductor was tested only twice, immediately after erection and after 16 months of natural weathering. The decrease in corona loss pattern obtained was therefore more typical of actual service. It is questionable whether or not direct comparisons of the three conductors can be made—the data may not be comparable at all.

An examination of the continuously-recorded data from the Tidd tests[6] shows the great variation in corona from day to day under nearly the same apparent conditions. In view of this it does not appear that, based on the Victorville tests (two groups of tests, each made during a single day, separated by an elapsed time of about 18 months) the authors can conclude "The advantage of the segmental conductor . . . is clearly indicated." Other investigators have arrived at the opposite conclusion.[7,8]

W. S. Peterson, Bradley Cozzens, and **Joseph S. Carroll:** In addition to the general comments regarding the measurements and information contained in the paper, Mr. Tilles poses several questions which can be answered in part as a matter of conjecture and part by observations made at the time of the test and at subsequent intervals. Most of this information, however, is not substantiated by rigorous observations and tests and, therefore, was considered as not proper for inclusion in the paper.

Mr. Tilles questions the correlation between air density, total ionization, ionization of various polarities, and mobilities. The air density correction factors applied were based upon first power correction of the normal air density ratios rather than the two-thirds power as has been indicated by some laboratory tests. The differences in temperature and normal air densities were not sufficient, nor was the test setup sufficiently flexible to carry on a study of this variable. Although antennas were erected to measure d-c voltages as a result of accumulated ion charge, little correlation was established between corona noise levels and the rapidity with which this charge would accumulate or the polarity of the charge. These measurements did establish the fact, however, that large quantities of charged particles are present in the desert atmosphere giving rise to accumulations of potentials on insulated conductors or objects and assisting in the precipitation of dust particles upon insulators and conductors.

Mr. Tilles questions the variation in loss between day and night and as affected by sunlight or ultraviolet radiation. Again, no direct measurements were made of these conditions, but from noise observations, which correlate quite well with corona loss, and from visual observations of corona brushes, there seemed to be little change and in many cases an increase rather than a reduction in the noise level with darkness. Of course, no reasonable comparison of corona brush length could be obtained between daylight and dark periods. Regarding the effect of wind velocity and electrification of the atmosphere, the audible noise in some cases tended to increase with winds. When dust particles were blown of sufficient quantity and possibly carrying electric charges, both the 287-kv and adjacent 138-kv lines have been seen to exhibit aggravated corona conditions. This is attributed to the discharge between the charged dust particles and the conductor. This latter phenomena can occur at practically any location in the dry desert area. The phenomena as described in the paper, however, namely the observed corona streams, occurred largely in the area adjacent to Victorville which is approximately 100 miles (90 miles air line) from Los Angeles and was most frequently present following a north wind. Subsequent tests indicated precipitation of dust particles following such north winds which carried some radioactive material, but laboratory tests in which conductors were coated with radioactive materials did not correlate with observed conditions in this area. As time permits, it is hoped that additional studies can be progressed along these lines.

Mr. Naef indicates that by comparison the tests conducted by the American Gas and Electric Corporation and co-operating agencies at Brilliant, Ohio, correlate closely with the values of corona loss obtained at Stanford University rather than those experienced under desert conditions. It was the surmise of the authors that this phenomena was associated largely with the dry desert atmosphere which carries with it highly ionized dust particles and because of the lack of moisture is subject to maintaining larger accumulations of these charges as a result of wind friction and dust movements. The more humid atmospheres of the midcontinent and east coast, as well as that in the vicinity of Stanford University, are not conducive to maintaining these charges.

As stated by Mr. Naef, it is necessary to consider climatic conditions in the selection of the conductor diameter and surface. In the case of the Hoover transmission lines, the major portion of these circuits traverse a desert area which has an average rainfall of from 1 to 4 inches per year. The presence of rain or high humidity is so relatively infrequent that it was not feasible to attempt to conduct tests under these conditions and likewise the percentage of time which they are present is so small they need be given little consideration in the over-all economics of the transmission system. Mr. Naef and his organization are to be complimented on their extensive studies under varying weather conditions which when completed will furnish sufficient information to evaluate these factors in connection with the design of future high-voltage transmission lines.

Several questions regarding the accuracy of measurements and methods used, as well as the ultimate results, were raised in the discussion presented by the engineering staff of the Anaconda Wire and Cable Company.

First, the suggestion that duplicate methods of measurement be used, of course, presents appreciable difficulty when making full-scale field studies both from the time involved and the cost of such procedure.

The reference to the use of short sections of conductor utilizing Schering bridge methods and concentric cylinder arrangement is ideal for basic theoretical studies in the laboratory. It is questionable, however, whether this would have confirmed the conditions being investigated for several reasons. First, if the conductor is maintained at high potential, the space charge established between the conductor and cylinder, as a result of corona upon the conductor and the physical dimensions of the test equipment, is of material effect in determining the nature and actual corona loss which exists. Any atmospheric phenomena which would be present and which would be influencing the corona loss probably would be swept clear of the area within the cylinder and would be overshadowed by the space charge established between conductor and cylinder. Second, if the cylinder is maintained at high potential and the conductor at ground potential, the atmosphere surrounding this cylinder would most assuredly be cleared of ionized or other materials which might be affecting the corona loss. The use of the water resistor multiplier method gave direct comparison with the studies previously conducted at Stanford without having to attempt field balancing and adjustment of bridge circuits.

The suggestion of sphere gap determination of dielectric strength of desert air would be subject to the same conditions as mentioned regarding concentric cylinders. If moderate-sized spheres and voltages up to

approximately 100 kv were used, the spacing between spheres would be of such magnitude that ionized particles would be swept out of the gap area during each half cycle. To go to larger spheres would be a cumbersome and difficult problem and of questionable value, particularly when using a voltage source at the generating end of a transmission line some 180 miles distant as a means of controlling voltage. Tests have been made up to 50 kv using sphere gaps which showed no measurable variation from the normal calibration value.

The question of harmonics is also raised. Cathode-ray oscillograph observations indicated the presence of limit harmonic voltages. The wave, however, was not mathematically analyzed. Losses resulting from normal harmonics through the seventh would be accurately measured by the water column wattmeter method and would correspond to those normally encountered on an operating transmission system.

Space does not permit the development of the equation for temperature correction and water flow. The fundamental formula for resistivity change with temperature was verified. Applying this to a straight water column carrying a definite current results in the equation developed.

Regarding temperature air density corrections, voltage values were corrected by direct application of the air density ratio, with the exception of those tests which were within 2 degrees Fahrenheit of the actual value to which correction was being referred. Since many of the tests were within 5 to 10 degrees Fahrenheit of the actual corrected values, little error can be introduced by the application of air density corrections using this direct ratio.

It is agreed it would have been much more desirable had time and equipment permitted to have made tests measuring losses on all cables independently without subtractions. During certain periods of the day, however, the losses on the cable specimen adjacent to the wattmeters was very constant, consecutive curves being almost identical. We feel justified, therefore, in using these data as accurate in establishing by subtraction the loss on the more remote sample and neglecting those tests during the early morning and late evening hours when some variations did exist. The wide variations referred to during the day observations of the Tidd tests (reference 6 of the previous discussion) largely occurred as the result of high humidity, fog or rain, which conditions were not present at Victorville.

The discussion refers to early tests in Europe (references 7 and 8 of the previous discussion) reported in 1927 and 1935 in which stranded cable is reported to have lower corona loss than segmental-type of the same diameter.

The segmental-type cables which were used at this early date and which were studied even earlier at Stanford[1] were of the rectangular flat-strip spiral-wound type or involved segments with sharp edges. Even the lock-wire tramway-type cable investigated in 1924[1] after being erected did not present a completely smooth surface. The individual strands rise slightly above the true circular contour and present sharp edges upon which corona forms at relatively low voltage. Investigators have reported that under rain conditions the losses on segmental-type cable may be equal or higher than those found on stranded-type conductors. The climatic conditions experienced on the transmission line, therefore, should be investigated very carefully. In connection with the Hoover Dam–Los Angeles transmission lines of the Department of Water and Power, the length of circuit over which rain is experienced frequently is relatively small, the major portion traversing desert areas where rains are very infrequent. Under these climatic conditions there is little question of the definite advantage of the type-*HH* segmental conductor both as established by tests at Stanford University and those conducted at Victorville.

A 5,000-Kva Underground Substation

JOSEPH F. SINNOTT
MEMBER AIEE

LARGE increases in electrical usage in a relatively small area of downtown San Diego began overtaxing the 4-kv underground radial feeders of the San Diego Gas and Electric Company supplying it. Furthermore, Substations A and C, the source stations for the overloaded feeders, were carrying full capacity and were 4,560 feet and 2,080 feet respectively from the distressed loads.

After lengthy consideration, it was decided to establish a new substation close to the center of the load, taking advantage of the fact that two lightly loaded 12-kv 500,000-circular mil 3-phase tie lines ran close by. These tie lines originated at Station B, a generating station with a capacity in excess of 100,000 kw, serving among others the two substations mentioned previously.

Since real estate values in downtown San Diego are high, it was agreed to install the substation underground, provided that a location with adequate ventilation could be obtained or built. Investigation soon revealed that no ready-made vault space could be obtained in any of the larger buildings nearby, and that a new vault would have to be constructed.

The district to be served was already fairly well built up, making large load increases rather unlikely. Consequently it was not deemed unreasonable to install a 5,000/6,667-kva capacity substation to feed the 4,890 kva in transformers installed in the area. It also was decided to feed the load with three 4-kv underground radial feeders of about 2,000-kva capacity each.

Area and Method of Serving Load

The load to be served, consisting mainly of office buildings and stores, is concentrated under the crosshatching on Figure 1, a portion of the street map of the city of San Diego. This figure also shows the location of Substation C at 4th and Ash Streets, Station B (the generating plant) at Kettner Boulevard and Broadway, and Substation A at 10th Street and Imperial Avenue. These are the three stations related to our discussion, others in downtown San Diego not being shown in order to simplify the picture.

Figure 2 is an enlarged map of the crosshatched area of Figure 1, showing the feeders serving it before the new substation was installed. From Substation C, 2,080 feet away, there were five single-phase and three 3-phase feeders to the area, whose cable sizes ranged from number 4/0 on the main leads, to as small as number 6 on some of the smaller branches. These feeders also fed some loads nearby.

Substation A, 4,560 feet away, had two 3-phase feeders serving this load, circuit *A-7*, a number 4/0 feeder; and circuit *A-4*, a 500,000-circular-mil cable. As in the case of the feeders from Substation C, there were loads outside the area on both circuits.

Figure 2 also shows the two 12-kv tie lines running between the generating plant (Station B) and Substation A, with the taps to Substation C. These tie lines were at one time the main source of energy for Substation A and emergency feeds for Substation C, but since the new Silver Gate Generating Station was built, they had been operated as emergency tie lines only, making them ideal for feeding any new substation close by.

Taking into account the location of the load, the proximity of the two 12-kv cables and the fact that the San Diego Gas and Electric Company garage was located within a block of the area to be served, it was decided to locate the new substation in a vault under the garage floor and call it the Electric Building Substation.

Figure 3 shows the three 4-kv feeder from the new Electric Building Substation to the area, one each on 5th, 6th, and 7th Streets. Each feeder has suitable ties and sectionalizing switches which are not shown in the figure. Whenever the old feeders from Substation A and Substation C remained in service, it was only to supply alternate emergency power to some of the larger buildings. The only load outside the area to be supplied by the Electric Building Substation was the Fox Theater at the corner of 7th and B Streets.

Substation Site

The new substation was built in a vault dug in the rear of the garage, because of the advantages of this location. These advantages were briefly:

1. It was wholly on San Diego Gas and Electric Company property.

2. The back of the garage abutted the company office building, whose basement provided easy access to the new vault from the air compressor room.

3. There was an old incinerator in the basement of the office building which was no longer used. The incinerator stack which was on the other side of the office building wall from the vault location provided an ideal exhaust flue for the vault, it being $3^1/_2$ feet by 4 feet in cross-section, and rising eight floors above street level.

4. By drawing the necessary cooling air for the transformer from the office building basement and exhausting it up the flue, we could greatly improve the basement ventilation as well as maintain proper transformer temperatures.

Figure 4 shows a plot plan and general layout of the office building basement and garage (at street level). The vault is located at the west end of the garage adjacent to the office building wall. The incinerator flue also can be seen on this

Paper 50-142, recommended by the AIEE Substations Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 13, 1950; made available for printing April 10, 1950.

JOSEPH F. SINNOTT is with the San Diego Gas and Electric Company, San Diego, Calif.

Figure 1. Portion of a street map of downtown San Diego, showing area to be served

figure at the northwest corner of the vault.

Preparing the Site

All cars were removed from the garage, and work was begun by digging the hole for the vault at the back of the building. This excavation had to be approximately 45 feet long by 23 feet wide by 16 feet deep for the main vault, and had an annex in which the blowers for the ventilating system were located which was about 7 feet wide by 23 feet long and varied in depth between 8 and $10^1/_2$ feet.

Because of the limited clearance between the garage floor and the lowest roof trusses, about 12 feet, it was necessary to dig the hole with a gasoline-driven Hoe-back. The Hoe-back would deposit the dirt on the garage floor from where it was lifted into waiting trucks by a pneumatic-tired High-lift. Trucks entered the north door of the garage, were loaded, and then departed through the south door.

The excavation was completed in 24 hours, working three shifts, and it was another 12 days before the vault was completed and temporary planking placed over the equipment opening so that cars could once more use the garage.

During the period of vault construction, the underground ducts from the future substation to the street also were installed and the garage floor resurfaced.

The Substation Vault

The vault itself is of reinforced concrete construction with walls one foot thick on three sides, utilizing the existing office building wall on the fourth side.

Before the floor slab was poured, a ground grid of number 1/0 wire was installed at the bottom of the floor slab excavation and connected to eight copperweld ground rods driven 10 feet into the moist soil.

Two 5-inch 6.7-pound channels also were imbedded in the floor slab and accurately leveled. These channels provided mounting supports for the transformer and metal-clad switchgear, eliminating the necessity of shimming or grouting the transformer or metal-clad equipment in order to make them line up. The channels also were used as a screed for leveling the concrete on the floor slab. Figure 5, a plan view of the vault proper, shows the location of the ground grid and mounting channels.

It is sometimes rather difficult to line up the channels in the floor slab and keep them lined up while the slab is being poured; however, the method used in this vault gave good results.

After reinforcing steel had been put in place, holes were dug in the dirt below the slab excavation with a posthole digger along the line on which the channels were to be installed. Bolts, long enough to extend about two inches above the channel surface, were then set in the holes, the holes filled with concrete. When the concrete was set, the channels were installed and leveled with a transit, using a nut on the top and bottom of the bolts to hold the channels firmly in place.

It was found that the channels remained in place very well during the pouring of the floor slab, and when the slab had set, it was a simple matter to cut or burn off the extra length of bolt extending above the channel.

Figure 2. Feeders serving the area before the Electric Building Substation was installed

The roof of the vault was of reinforced concrete construction supported by 12-inch wide-flange 58-pound beams running the short way of the vault. These beams were supported by the vault walls on one end and piers set adjacent to the office building wall on the other end.

An opening 10 feet 4 inches by 14 feet 6 inches in the clear was left over the transformer location to provide an entrance for the heavy equipment. This opening was covered with seven precast 6-inch removable concrete slabs after the equipment was lowered in place, and the cracks between slabs were sealed with asphalt. Figure 6 shows these slabs in place in the opening.

On one corner of the roof of the vault there was installed an 18-inch opening with a removable manhole cover. This opening was to provide an entrance to the

Figure 3. Feeder serving the area after the Electric Building Substation was installed

Figure 4. Plot plan and general layout of Electric Building basement and 7th Street Garage (at street level)

vault for the 12-kv and 4-kv rubber cables from the mobile substation which could be used to pick up a good part of the Electric Building Substation load in the event of transformer failure. The mobile substation could be parked in the garage and connected to the underground substation in various ways by means of dummy circuit breakers.

A sump was provided in the vault to take care of any small amounts of water which might inadvertently seep into the substation vault, and a $4^1/_2$-inch curb was provided at the door to the basement to be sure that no oil could flow into it in case of a ruptured transformer tank.

The 2 by 9 foot opening from the vault to the incinerator stack for air exhaust and the ventilating fan annex previously described complete the vault proper. Figure 7, showing an elevation of the west end of the vault, including the fan annex, will show more clearly the location of the elements just described.

Figure 5. Plan view of vault, showing mounting channels and ground grid

Figure 6. View of removable precast concrete slabs in place in the opening through which the apparatus was lowered

Installing the Equipment

All of the substation equipment was brought into the garage and lowered in the vault through the opening provided for the purpose. The supervisory control panel and two units of metal-clad switchgear were lowered first without incident.

The main transformer, however, was a little more difficult to set in place because of the limited headroom in the garage. As has been mentioned before, the garage door lintel is 11 feet, $2^3/_4$ inches in the clear above the floor at the lowest point. The transformer is 11 feet $1^5/_8$ inches high to the top of the pressure relief device, leaving very little clearance for handling under the door lintel.

The transformer was unloaded in the street and skidded into the garage on greased steel angles. Wooden cribbing, 12 by 12, was installed in the vault below the opening until the cribbing was flush with the garage floor. The transformer was then skidded onto the cribbing. Figure 8 shows the transformer being skidded along the garage floor after having come through the south door.

Two Krane Kars with short booms were set in place on each side of the transformer and their booms bolted together above the center of the unit. Cables were run between the front axles of the two Krane Kars to keep the axles from spreading apart when the load was picked up. In order to improve the balance of the transformer, the radiators were not installed until the transformer was in place in the vault. This operation may be seen in Figure 9.

When everything was in readiness, the Krane Kars picked up the 35,000-pound transformer and held it suspended while the skids and first layer of 12 by 12 cribbing was removed. Then the cranes lowered the unit about 12 inches and held it suspended while the second layer of cribbing was removed. This process was repeated until the transformer was in place on the vault floor. At no time during the descent was the transformer more than slightly over 12 inches above the very substantial cribbing. The positions of the Krane Kar booms remained fixed throughout the 36 minutes required to lower the unit in place. The radiators were set in place by utilizing one of the Krane Kars. Figure 10 shows the cribbing being removed while the transformer is lowered through the opening.

The Substation Proper

Figure 11 is a 1-line diagram of the indoor metal-clad master unit substation which was installed in the vault. It will be noted that there are two incoming 12-kv circuits, operating in parallel to feed a main 3-phase power transformer, which in turn feeds a main 4-kv bus from which three outgoing feeders and a transfer feeder originate.

The high-voltage metal-clad switchgear is made up of four units. Units 1 and 3 provide terminal facilities for the two incoming 12-kv cables, and units 2 and 4 house the 10-kva control power transformers with their draw-out fuses.

Figure 8. Skidding the main power transformer along the garage floor

Figure 12 is a front view of the 12-kv metal-clad switchgear as installed. The sump referred to previously may be seen in the lower left-hand corner of the figure. The circuit breakers on the incoming feeders are a-c-rectifier solenoid-operated draw-out air circuit breakers with a published interrupting rating of 250 megavolt-amperes. The 12-kv 500,000 circular mil 3-phase paper insulated lead covered cables enter the metal-clad compartments through 3-phase right-angle potheads mounted on top of the units. The pothead wiping sleeves are on a level with the cable ducts under the garage floor. By entering the units at the top instead of the bottom, the necessity of draping the cables along the walls of the vault was eliminated. As is usual on indoor metal-clad equipments, instruments, relays, and so forth, are mounted on the face of the doors of the circuit-breaker compartments, as can be seen in Figure 12.

The main 12-kv 1,200-ampere bus is throat-connected to the 3-phase 12,500/-4,330-volt power transformer. This unit is rated 5,000/6,667 kva and has $2\text{-}2^1/_2$ per cent hand taps above and below 12,500 volts as well as $\pm 7^1/_2$ per cent automatic tap changing under load to provide regulation for the 4-kv bus. The height of the transformer was limited by the clearance of the garage door lintel, which is 11 feet, $2^3/_4$ inches, and the garage roof trusses whose minimum clearance is 12 feet. Figure 13 is a front view of

Figure 7. Elevation of the west end of the vault, including the fan annex

Figure 9. Transformer ready to be lowered into the vault

the transformer, showing the tap changer compartment with the controls mounted below inside the door. The 4-kv switchgear is in the distance.

In order to obtain the maximum cooling efficiency for the transformer, the radiators were all mounted at the back of the unit and the stream of ventilating air is directed on them by adjusting the louvres on the air intake ducts. Figure 14 shows the air intake ducts on the south wall with the louvres set to direct the air stream downward toward the transformer radiators, from which the picture was taken.

The transformer proper and tap-changing compartment of the unit are both oil-filled. At the time the specifications for the substation were being written considerable thought was given to the use of askarel instead of oil as a cooling medium because of the lesser fire hazard. But inasmuch as oil was required in the tap-changing compartment, the place where trouble is most likely to occur if there is any trouble, and because it would be a simple matter to contain the oil from a ruptured transformer in the vault, it was decided that it would not be worth while to use a half askarel, half oil unit.

From the transformer a throat connection leads to the low-voltage metal-clad switchgear which consists of five units housing 1,200-ampere 4-kv main and transfer busses. There are three 4-kv feeder units with their a-c-rectifier solenoid-operated 100-megavolt-ampere interrupting capacity air circuit breakers and interlocked disconnecting switches to permit connecting the outgoing feeder to the 4-kv transfer bus. There also is a 4-kv transfer feeder unit which contains the 4-kv transfer air circuit breaker, similar to the feeder circuit breakers. The fifth unit, an auxiliary compartment, houses the 48-volt battery, metering current and potential transformers and station power and light throwover. The 4-kv metal-clad switchgear is shown clearly in Figure 15.

The 4-kv transfer circuit breaker is provided to permit testing and maintenance on the three outgoing feeder circuit breakers and controls without the necessity of transferring the feeder load to some other substation.

As in the case of the 12-kv potheads, the 4-kv right angle potheads are mounted on the top of the metal-clad switchgear. The 4-kv transfer bus is located in a compartment with the transfer disconnecting switches at the top of the switchgear. The transfer bus compartment and back of the 4-kv potheads can be seen clearly in Figure 15.

The last major item in the substation is the code selector supervisory control equipment. The relays which form the integral part of this type of supervisory control are mounted on a separate panel set up in one corner of the vault and connected to the metal-clad switchgear by means of overhead conduits. The control station for the Electric Building Substation is in the dispatcher's office, which is located adjacent to Substation A.

Ventilation System

Air for ventilation and cooling is drawn from the basement of the Electric Building through a $5^1/_2$ by 6 foot grilled opening near the ceiling of the stationery department storage room by means of two 30-inch fans each driven by a 2-horsepower 220-volt 3-phase motor, and discharged into the vault through two openings each about 2 feet square. By providing such a large opening from the stationery department to the ventilating fan annex and by providing screens instead of a solid wall in the upper part of the basement partitions, it was possible to keep drafts in the stationery and other departments quite low, even though providing 300 cubic feet per second of air to the vault.

Figure 10. Removing the cribbing from beneath the transformer as it was being lowered into the vault

Figure 11. One-line diagram of the Electric Building Substation

Figure 12. Front view of 12-kv metal-clad switchgear

Two fans were provided instead of one larger one in order to be sure of some ventilation and cooling air even though one fan should fail.

The 2 by 2 foot intake openings for the vault are located near the ceiling and are provided with louvres tending to direct the stream of air toward the transformer radiators where the transformer fans pick up the cool air and carry it through the radiator bank, still maintaining the same direction of flow. Finally, the warmed air is discharged through the incinerator flue. Figure 14 shows these openings.

Figure 13. Front view of power transformer showing tap-changing compartment and 4-kv metal-clad switchgear in the background

Figure 14. View of air intake openings taken from the top of the transformer radiators. The 4-kv outgoing cables appear in the center of the picture

The fan motors are equipped with pushbuttons located in the vault to the right of the door as you enter. These pushbuttons operate magnetic switches next to the motors in the annex. Energy for the fan motors is obtained from the Electric Building power supply and not from the substation control power transformers.

Over each intake opening, a 3/16-inch metal door is suspended and held open by a magnetic latch which can be shut in event of a fire. This device will be described more in detail later.

So far with about 4,200 kva on the transformer bank the maximum recorded temperature has been 40 degrees centigrade, a very reasonable figure for a vault transformer operating at 84 per cent load.

Fire Protection

In any substation in which oil-filled electric equipment is installed, there is always present the danger of an oil fire. To cut this possibility to a minimum, several precautions have been taken in the Electric Building Substation.

In the first place, the 12-inch beams supporting the roof of the vault were incased in concrete in order to prevent damaging them in the event of an oil fire.

A fire door, held open by a magnetic latch, is installed between the vault and the Electric Building basement to prevent any fire or smoke from entering the basement.

Two circuit-opening thermostatic switches are installed in the vault near the ceiling, one above and slightly to the north of the transformer proper (downstream in the air flow), and the other close to the exhaust flue.

These thermostatic switches are in series with the power supply for the magnetic latch which keeps open the fire door, the magnetic latches which hold open the metal doors over each air intake, and the magnetic switches for the ventilating fans. Should the temperature in the vault rise above a predetermined value, the fans are shut down, the air intake closed off and the fire door to the basement closed at once. Operation of this equipment sounds an alarm in the dispatcher's office over the supervisory control equipment.

In the event of a serious fire, the cover can be removed from the opening in the northeast corner of the vault which was installed to take the emergency leads from the mobile substation and the vault flooded with CO_2 brought in from an outside source.

Circuit Relaying and Control

Both 12-kv incoming feeders are operated with their circuit breakers closed on the Electric Building bus at all times, so that the failure of either source will not result in an outage to the substation. As has been mentioned earlier, the 12-kv lines feed from Generating Station B to Substation A, Substation C, and the Electric Building Substations. Two-wire differential-type pilot wire relays

Figure 15. View of the front of the 4-kv metal-clad switchgear, showing 4-kv transformer bus compartment and 4-kv potheads above the switchgear proper

which are normally not recommended for application to lines having more than three terminals have been applied to these 4-terminal lines. Knowing that normal or even most abnormal operation would never require more than three of the line terminals to be closed at one time, the pilot wires to the three receiving substations were carried through "a" auxiliary switches at those substations so that the idle relay would not shunt the active relays when its breaker was open.

The transformer bank itself is protected with induction overcurrent relays equipped with instantaneous trip attachments connected to trip both incoming 12-kv oil circuit breakers, which can be set half or three-fourths of the way through the transformer bank.

The relaying on the 4-kv feeders is conventional 3-phase relays and a residual or ground relay, all equipped with instantaneous trip attachments to clear high current faults as soon as it is possible.

Each circuit breaker is equipped with a supervisory-local transfer switch by means of which the control of the individual units may be changed from supervisory control to control by the pistol grip control switches on the panels. It might be noted that the control is wired in such a way as to permit circuit breakers to be tripped locally no matter what the position of the supervisory-local switch might be, but only permits the circuit breaker to be closed locally when the supervisory-local switch is in the local position.

Instantaneous single-shot reclosing relays are installed on the 4-kv feeder circuit breakers which are in service whether the substation is on supervisory or local control, it being considered important to limit outages to these feeders to a bare minimum. Even though the feeders are all underground and faults probably would be of a permanent nature when they occur, the reclosers were installed to re-energize the feeders on the chance that some faults might be self-clearing. Incorrect co-ordination between the relay instantaneous trip attachments and distribution fuses during high-current faults might be considered a self-clearing fault.

Summary

The Electric Building Substation whose design and installation has been outlined is operating very satisfactorily. Transformer operating temperatures are very low, and voltage regulation throughout the area served is well within allowable limits.

The company was extremely fortunate in being able to take advantage of the incinerator flue to exhaust the heated air from the transformer vault, as this is always one of the major difficulties to be overcome on any large vault installation.

Discussion

Ray K. Klumb (Southern California Edison Company, Los Angeles, Calif.): I have studied Mr. Sinnott's paper with considerable interest and am pleased to find there are other people who believe in the practicality of the underground substation for multicircuit distribution service. The San Diego Gas and Electric Company was indeed fortunate in having structural conditions so well suited and are to be commended on seeing the advantages of the situation and putting it to such good use. This application points a way for other utilities in that their own structures may be part of the answer to providing service facilities in the more congested areas.

It appears that increased load density in the area was the necessity for the substation, and I wonder if the station was made large enough in physical size to take care of future increase. The thought being that provision for future capacity is relatively easy when building a new substation of this type, but oftentimes extremely difficult after the station is on the line. Load within reach of the substation, but not now served from the substation may in the future reach values that will make it desirable to feed from this point rather than from the existing source. When such conditions occur, and they do quite often, it is a comfortable feeling to have sufficient room to add the necessary facilities.

I would like to mention a few points that the Southern California Edison Company feel are important in underground substation application and operation.

When an underground substation is dictated plans should be laid for at least an ultimate of the capacity needed for the area that can be economically served from that point to the extent that carrying charges on structural space are within the cost of an addition or a new substation. Another factor to consider in deciding upon a definite capacity is whether or not the load can be satisfactorily served if additions or replacements are necessary. Maintenance has to be considered, in that facilities to handle maintenance without load interruption are needed. Also reasonably good protection should be available when various parts of the substation are out of service for maintenance. Testing facilities for relays and circuit breakers are a part of the plan, and the cost of handling the maintenance should be reasonable.

Mr. Sinnott mentioned the provision for getting cables from a mobile substation into the vault in case of transformer failure, and he stated that the mobile substation could pick up a good part of the substation load. Is it best practice to put reliance in a single transformer in an underground substation? Also, when the time arises to overhaul the tap changer, how will it be done and service maintained? Within our company, we do not feel justified in making installations of this kind without switching facilities for disconnecting the equipment, and also we do not feel secure without a spare or means of carrying the load should the largest unit fail.

Tap changing under load transformers feeding more than one circuit requires balancing circuit loads in order to deliver correct voltage at all points on the feeders. This condition and requirement has deterred us from handling more than two circuits in this manner in the areas where circuit loading is of the order of 1,500 kva or better. I would be interested in Mr. Sinnott's comments on this point.

Provision for fire protection as covered in Mr. Sinnott's paper is from the exterior and with the use of outside equipment. This I do not believe would be satisfactory in case of fire. We prefer fully automatic fire protection using CO_2 saturation, with control from suitably placed thermostats.

The Southern California Edison Company has operating one completely-underground 16/4-kv substation with 9,000-kva capacity, feeding six 4-kv individually-regulated circuits. The transformers at present consist of three 2,000-kva and three 1,000-kva single-phase units. Ultimate capacity for which room has been provided is six 2,000-kva single-phase units. A spare 2,000-kva transformer is maintained in the Alhambra warehouse to cover the large bank. The station is fed at present by two 16-kv circuits and the third circuit is being added. Switchgear is all metal-clad using oil circuit breakers. The protection employs directional overcurrent on the incoming lines and overcurrent and ground on the 4-kv circuits. The station is fully automatic. Incoming lines are self-restoring and 4 kv circuits are equipped with reclosers. Alarm signals are transmitted over wired circuits to the nearest attended substation.

Transformers are protected with differential relays and an automatic CO_2 fire extinguishing system is provided. Cooling is provided by fans operating on thermostat control from room temperature. The operation of this station has been satisfactory, but in an attempt to reduce the cost of such installations, a new design is on the drawing board for an eight circuit 18,000-kva 16/4-kv underground substation using four 3-phase tap changing under load transformers so rated and arranged that two will carry the total load over the peak if necessary. Arrangement is such that normally one transformer carries two circuits. In case of failure of one transformer the circuits carried from the bad order unit are automatically picked up on two of the remaining transformers. Control and protection will be arranged to cover failure at any one point and still carry the load. The station will be automatic and self-sustaining for all conditions of operation and maintenance and nothing except complete failure of the 16-kv switchgear should shut it down. Each transformer will have 4,000-volt capacitors

provided with automatic switching facilities for voltage level control. Control power will be supplied for all operating functions by a 125-volt storage battery. The substation will be constructed in connection with an office building, the basement of which will contain a portion of the equipment, but the rear area will be completely underground with the roof used for parking. Access to the station, both by stairway and hatchway, will be from the parking area. Only one half of the substation equipment will be installed initially, and the other half will be installed when load conditions dictate. Arrangement and connections will be such that additions can be made with only part of the equipment out of service at one time. Cooling air will be provided with low velocity fans to keep down the noise level outside the substation.

I wish to compliment Mr. Sinnot on his paper, particularly on the detail with which he covered the subject. I would like my remarks to be accepted merely as thoughts and ideas on underground substations. It is evident that the compelling forces of congestion will necessitate more underground substations. Criticism and ideas will be most welcome.

J. F. Sinnott: In his discussion, Mr. Klumb questions as to whether or not the substation was made large enough in physical size to take care of future increase.

There were several reasons for limiting the size of this substation.

1. As pointed out in the paper, the area to be served is fairly well built up, making large load increases rather unlikely.

2. A larger substation would require more cooling air, increasing the velocity through the flue to the point where the noise of the exhaust would be objectionable. Furthermore, the air intake problem would become complicated.

3. When the new substation becomes loaded, it is planned to shorten the extent of the three feeders and feed the far ends from existing or new stations that would not have to be installed underground.

Whenever it becomes necessary to maintain the tap changer, the far ends of the three 4-kv feeder loads will be picked up on feeders from Substations A and C through tie switches, and the bulk of the load carried on the mobile substation. This can be done without an outage to any load and with very little voltage disturbance.

We have found modern 3-phase transformers extremely reliable and can see no reason for dividing the load between two units as long as the feeders can be tied to other substations in an emergency and so long as we have a mobile unit available.

That the longest 4-kv feeder is less than 900 feet in length and that all the load is of similar nature makes, in our opinion, individual feeder regulation unnecessary.

Progress Report on Tidd 500-Kv Test Project of the American Gas and Electric Company—Corona, Radio Influence, and Other Factors

PHILIP SPORN
FELLOW AIEE

A. C. MONTEITH
FELLOW AIEE

Synopsis: The field test project for studying corona, radio influence, and other technical features of electric power transmission in the extra-high-voltage range now has been in progress on The Ohio Power Company system of the American Gas and Electric Company at Brilliant, Ohio, for over two years. This paper is a progress report of this activity. It presents problems that are unique in the study of corona, particularly the effects of the conductor surface and weather upon the corona loss. It emphasizes the importance of foul weather in determining the average loss for use in evaluating the economic aspects of corona loss. Extensive tests also have been made of the effects of corona upon radio communication services. Radio influence is probably the factor limiting the choice of a satisfactory conductor for extra-high voltages.

DURING the past two years a great deal of information of value on the technical features of high-voltage line design has been obtained from the field research which is being carried out by the American Gas and Electric Service Corporation in co-operation with eight manufacturers of high-voltage equipment. This program was fully described in a symposium of seven papers in 1947.[1–7] The objectives and test facilities for carrying on the field test work were covered in considerable detail in that series of papers.

The broad objective is to obtain additional, more extensive, and more precise information on some of the technical problems involved in extra-high-voltage transmission. It was feared that the satisfactory solution of some of these problems possibly might act to put a limit on the voltage one might otherwise choose in seeking ways to improve the economics of transmitting large blocks of electric energy which are certain to be needed in the relatively near future.

In brief, the test facilities consist of a 5,000-kva bank of three single-phase transformers which can vary the 3-phase line-to-line voltage in steps from 265 to 532 kv. Three test lines, two 1.4 miles long and one 800 feet long, are available. Supersensitive metering equipment is used to indicate and record corona loss. The metering also includes indicating and graphic radio-influence meters, commercial amplitude-modulated and frequency-modulated receivers, a television set, a voltage gradient meter,[8] and graphic meters to record temperature, barometric pressure, precipitation, and humidity. In addition, an automatic camera, set to photograph sample conductors and insulators every 20 minutes, is used in the determination of general weather conditions, such as rain, snow, sleet, and fog. A setup is also provided to measure the loss on a string of insulators. Line conductors from 0.92 inch to 2.0 inches in diameter have been tested. A view of the field test station is shown in Figure 1.

The great amount of data already obtained from the field tests has been analyzed partially but still requires further study and correlation before arriving at definite conclusions. However, it was felt that although the analysis and field test work are not complete at this time, a presentation of the progress being made and some of the high points of the results obtained would be justified in being presented now because of the interest. This report accordingly has been prepared to fulfill this objective. It is planned within the next year to follow this brief presentation with more complete results and analysis giving detailed test data and summarized results. It needs to be emphasized, therefore, that the data presented here must be considered as preliminary; complete analysis of data already obtained and further work now in progress may modify the results.

Corona-Loss Test Program

In the corona-loss studies emphasis has been placed on establishing a method of estimating the magnitude of the annual corona loss on various conductor and line designs, and the manner in which the corona loss might be expected to vary with voltage and weather. Information upon which to base estimating procedures can be obtained by recording the corona loss on a full scale line at different voltages over long periods that include all kinds of weather. The corona test program has been planned to obtain the fundamental data required to meet these objectives.

Because of the many variables involved, and the fact that weather conditions cannot be controlled, the procedure was adopted of recording, for later analysis, those factors which are considered important, rather than depending upon making individual tests under a variety of weather conditions. Figure 2 illustrates typical information that has been obtained thus, or can be derived from the field graphic charts.

In order to provide information on the full voltage range over which the conductors might be expected to operate, the lines were energized continuously, and the applied voltage was changed every few days. Voltages of 280, 345, 396, and 452 kv phase-to-phase have been used. In addition to obtaining graphic records of corona loss at these four voltages, voltage-versus-corona-loss runs were made every four weeks using indicating instruments. These tests were made under both single- and 3-phase conditions. Most voltage runs were made under fair-weather conditions so that the results of successive tests could be compared. Some tests under adverse weather were made, but these tests are not readily comparable as rainfall is rarely constant for a sufficient time to obtain a complete test under constant conditions.

Factors Producing High Values of Corona Loss

Great variance was observed in corona loss measurements as noted by previous investigators.[8, 10, 11, 12, 13] The factors influencing this variance can be divided into two categories: first, those associated with the conductor surface, and second, those associated with weather conditions. Thus different conductors might have comparable corona loss under fair-weather conditions but different losses after aging or during foul weather.

Surface Factors

The surface of an energized conductor undergoes a change with time such that the loss usually decreases, the magnitude of the change varying with the particular type of conductor. From the fair-weather runs made periodically over a period of almost two years, the loss values corresponding to the 532-, 454-, and 376-kv points are plotted in Figure 3 for the 1.65-inch Heddernheim conductor. This figure shows how much loss might be expected on a new conductor when it is first placed in service.

The effect of continuous energization of the conductor is indicated in Figure 3 for 454 and 376 kv. In determining the time required for a conductor to stabilize, the 532-kv curve in Figure 3 may not be significant because the conductors have never been energized for long periods of time at this voltage.

The wide range of loss readings which are obtained at a given voltage on successive fair-weather voltage runs indicates that comparisons of conductors should not be based on single observations.

Another surface effect is the temporary increase in the corona loss on a conductor after it has been de-energized for a day or more. If the conductor is energized again, the initial value of the loss is considerably higher than normal, and the loss immediately starts to decrease, requiring several hours or more to become constant. Because of this effect, the corona starting voltage of a given conductor might be 100 kv or more below its normal value. Conversely, although to a much lesser extent, if a conductor is energized at a voltage high enough to produce profuse corona, the loss at a lower voltage is temporarily reduced.

This effect is shown in Figure 4, which presents the results of a single-phase test. With increasing and then decreasing voltages, each voltage being applied for a period of 20 minutes, readings were taken every five minutes. Each time the applied voltage was increased, the conductor on line 1 showed a marked decrease in corona loss from its initial value for the interval, but when the voltage was reduced, it showed a slight increase in loss above the initial value for the interval. At the lower voltages the conductor on line 2 was not in corona, but at higher voltages a loss decrement with time can be observed which is similar in character to the conductor on line 1 but different in magnitude. Therefore, to obtain consistent results it was found necessary to precondition the conductors by energizing them at maximum voltage for about 15 minutes prior to testing. This procedure unfortunately yields values which are lower than the loss which would exist if the conductors were energized continuously at each test voltage.

Weather Factors

Of the weather factors causing high corona loss, rain, sleet, and snow are the

Figure 5. Correlation between rate of rainfall and corona loss, both averaged for periods of 48 hours to several days of operation at constant voltage

most important. High corona loss has been recorded during fog, but it is believed that this condition was caused by condensation of moisture on the surface of the conductor which is not likely to occur on an operating line. Temperature, humidity, barometric pressure, and atmospheric voltage gradient have an effect which is small compared to that of rain. Figure 2, in which most of these factors are recorded, is a typical example of how they vary. Separation of weather factors requires detailed analysis of a large number of records because several of the weather factors change together.

Preliminary analysis shows a consistent correlation between corona loss and average rate of rainfall.[16] Remarkably smooth curves are obtained if the corona loss, averaged over periods of from 48 hours to several days of operation at constant voltage, is plotted against average rate of rainfall for the same period. This is shown in Figure 5 for line voltages of 398 and 454 kv. These curves are based on data taken under a variety of weather conditions and during different seasons. Except for a few points at high rates of rainfall, no attempt has been made to select rainy periods. Their remarkable consistency indicates that such curves might be an acceptable basis for estimating annual corona loss.

To illustrate further the effect of weather, Figure 6 shows curves of voltage versus corona loss taken with indicating instruments. Curve 1 gives the average loss for fair weather, and the other curves the loss for foul weather. These curves illustrate the wide variation of corona loss under different weather conditions.

Average Loss for All-Weather Conditions

More significant information is obtained from the graphic records of all-weather corona loss than from individual fair-weather voltage runs. From graphic records, the annual corona loss can be estimated and its economic importance determined. From an analysis of corona-loss graphic records and weather charts, examples of which are shown in Figure 2, curves of the type illustrated in Figure 7, which show the per cent of time that the loss exceeds values given by the ordinate, can be plotted. It will be observed that the fair-weather losses are small and that for periods of known rainfall the losses are high.

"Fair weather" in this figure is a condition in which no rain is indicated by a conventional graphic rain gauge. "Rain only" is a condition as observed by the test men during the day and operating personnel during the night, in addition to the records from the rain gauge. With the more sensitive photographic weather recorder now being used, the fair-weather curve will be lower. The relative periods of fair and rain conditions are reflected in the all-weather curve which is obtained by averaging the loss over the entire period.

All-Weather Losses for Different Conductors

Table I is a résumé of some of the data obtained from curves of all-weather losses for different conductors. The data were taken during the 3-month period from November 29, 1948 to March 1, 1949, with the lines energized at 390 kv phase-to-phase.

The average corona loss of different

types of conductors depends not only on the applied voltage but also on the relative duration of fair and foul weather. Table II, which summarizes the three months' data of Table I, shows how the information can be tabulated, but does not contain information extending over sufficiently long periods to permit a reliable comparison between conductors. The conductors were tested at other voltages during the periods indicated, but this table presents only the information obtained at 390 kv. Records of this nature have been continued and still are being made.

The average values of corona loss, such as given in Table II, can be expected to be the same on operating lines as they are on the test lines. However, for lines of practical length the maximum value of corona loss will be much less than on test lines because extremes of weather are not likely to exist all along a line simultaneously. An evaluation of the weather conditions along a proposed right-of-way is necessary before an attempt to estimate the average and maximum values of corona loss can be made.[9]

Radio Influence

When this investigation was started, the published information available on radio-influence characteristics of transmission lines was believed to be insufficient for the prediction of these characteristics for a line designed to operate at voltages appreciably higher than the voltages used at the present time. The most recent publications[8, 10, 13, 14, 15] present most of the information available and have been published since the Tidd project was planned and started. Because of the clearly indicated need for the consideration of radio influence in the design of extra-high-voltage lines, it was decided to undertake a major study of radio influence using the Tidd test lines. A laboratory test program is also in progress to co-ordinate laboratory and field data.

The radio-influence problem consists essentially of two parts: the determination of the radio-influence factors of transmission lines, and the evaluation of these factors in terms of their effects on the communication services. One practical approach to the second part is the evaluation of data and experience on existing high-voltage lines as a bench mark.

Scope of Tests

It was planned to determine the effect of voltage and weather on radio influence for various conductor types, sizes, and spacings over long periods of time using graphic radio-influence meters so that average fair-weather and all-weather data would be available for analysis. Measurements have been made over the frequency range of 0.015 to 400 megacycles per second. Some of the data over this portion of the radio spectrum have consisted of manual readings, generally obtained during fair weather. Fair weather is considered to be any weather other than fog, rain, sleet, or snow environment around the conductors, and with conductor surfaces free of water, ice, or snow. Lateral and longitudinal profiles of radio influence have been made with the available portable meters. The effect of line voltage on radio influence has been investigated both with portable meters and with the graphic radio-influence meters.

Test Equipment

The equipment for radio-influence measurements consists of standard radio noise and field intensity meters[16, 17, 18] and a trailer equipped with amplitude-modulated, frequency-modulated, and television receivers.

Figure 7 (below). Corona loss record for one month on line 2 at 395 kv line-to-line during fair, rain, and all weather conditions

Ordinate indicates per cent time losses exceed the abscissa

Figure 8. Radio influence variation with line voltage at distances of 0 to 160 feet at right angles to line 1

Figure 9. Attenuation of radio influence in per cent of values measured directly below outer phase conductor for line voltages from 138 to 450 kv phase-to-phase

Some Typical Data

The variation in radio influence with weather is being recorded with graphic meters at several voltages and for two conductor sizes. A portion of chart record for each of two lines is shown in Figure 2. It can be seen from this figure that snow and rain increase radio influence. The relative values of radio influence for the short period of time shown in this chart are not necessarily the same as would be obtained over a long period. There are considerable variations in radio influence during fair weather, and the causes for these variations have not been completely determined.

Radio Influence and Line Voltage

The relative change in radio influence with line voltage for different horizontal distances from the outside conductor is shown in Figure 8. The rapid rise of radio influence with increase of line voltage is apparent, as is the drop with increase in horizontal distance from the conductor. The slope of radio influence curve with voltage, for conductors of this size, is approximately the same as obtained by other investigators.[9,10]

Radio-Influence Attenuation with Lateral Distance from Outer Phase Conductor

Measurements of the lateral attenuation have been made at several frequencies with lines energized both single-phase and 3-phase. Some of the data obtained are shown in Figure 9. These data are from 62 tests at voltages of 138 to 450 kv line-to-line. The small spread of the test points indicates that the lateral attenuation is practically independent of line voltage.

Radio Influence Along the Line

Measurements obtained under the center-phase wire at 475 kv are shown in Figure 10. The variations of radio influence along the line are believed due to shielding by towers, change in conductor height, and reflections. The apparent attenuation is probably due to a change in radio influence during the three hours required for the test.

Radio Influence and Frequency

Measurements of radio influence over the frequency range show that radio influence values vary somewhat inversely as the frequency. Tests with amplitude-modulated, frequency-modulated, and television receivers indicate that radio influence may affect amplitude-modulated broadcast reception without appreciably affecting frequency-modulated and television reception.

Factors Affecting Tolerable Radio-Influence Levels

The evaluation of the effects on the communication services and tolerable limits of radio influence requires consideration of the characteristics of radio influence obtained and its effect on the various communication receivers, available signal intensities along the line, satisfactory signal-to-noise ratios, effects of weather, number and type of receivers in vicinity of line, distances of receivers from the line, transfer of radio influence to lower voltage circuits, and means for improvement of reception at a particular receiver.[19,20] It seems reasonable to permit higher levels of radio influence on extra-high-voltage transmission lines than on lower voltage lines for several significant reasons: 1. the direct coupling to receiver antennas will generally be less; 2. there will be fewer receivers near the line; and 3. there will be fewer parallels and cross-overs.

Figure 10. Radio-influence profile measured along test line under middle-phase conductor

Line energized at 475 kv phase-to-phase

Continuation of Investigation—Evaluation of Test Data

While some test data still remain to be recorded, most of the information has been obtained. The large amount of work involved in analyzing and correlating these data still remains to be done.

A summary of the large amount of data which has been obtained at the field test location may be of interest. Up to January 1, 1950, over 12,000 feet of graphic records from corona loss and radio influence instruments have been obtained. Over 200 corona-loss-versus-voltage runs have been made, including 3-phase and single-phase tests. In addition, all weather recording meters have been in almost continuous operation but are not included in the foregoing summary of graphic records.

By February 1950 only part of the data thus far obtained in the field had been analyzed and correlated. For this reason only typical data are presented in this report and the conclusions drawn must be considered tentative. Definite conclusions cannot be drawn at this time, but must await the more complete analysis of all significant data.

A series of complete reports giving detailed analyses of the data obtained on conductors tested and information on the application of these data to extra-high-voltage line design is planned for presentation before the AIEE in the near future.

Tentative Conclusions

1. Voltage-corona-loss runs are primarily of theoretical interest, and in general are less significant for comparing conductors than voltage tests of long duration. The all-weather corona loss of conductors is believed to be of more significance in studying the economic value of corona loss on a high-voltage line.

2. Corona loss is a function of the combined effect of surface and weather factors. New conductors generally produce more corona than aged conductors.

3. The radio-influence problem involves the determination of radio-influence factors to be expected on a line of specific design, and the evaluation of these factors in terms of their effects on communication services to be encountered. Much work has been done on both phases of the problem. Serious consideration must be given to this problem in the design of extra-high-voltage lines.

4. While some definite values on corona loss and relative figures on radio influence are presented in this paper, they must be considered tentative. A series of reports to be presented in the near future will give complete information on both corona loss and radio influence, and on the application of these data to extra-high-voltage transmission line design.

Discussion

P. L. Bellaschi (Consulting Engineer, Portland, Oreg.): Although lacking in essential details, which presumably will be forthcoming in reports to follow, this paper presents substantiating data and new findings relating to the problems of corona loss and radio influence at the higher transmission voltages.

The variations of radio influence with voltage and with distance from the line, presented in Figures 8 and 9 of the paper, are in general accord with the findings of prior investigators. We concur, too, that at the higher transmission voltages radio influence can become a determining factor, probably limiting the permissible operating voltage for a given conductor or limiting choice of satisfactory conductor for a given voltage. The paper further indicates that possibly higher radio-influence levels might need to be accepted for the higher transmission voltages; this is a point on which some differences in viewpoint can exist.

It is well recognized now that radio influence and corona loss are accentuated by foul weather (rain, snow, sleet, and so forth). In fact, where precipitation is a major factor, the annual rainfall, as the French have established, is a good index in determining average annual corona loss. However, the relationship between average corona loss and rainfall, remaining fair weather, and other influencing factors, does not appear to be a simple one.

A factor we consider of significance in the evaluation of corona is the annual distribution of corona loss in relation to the availability of power and to the peak load. Other factors which hardly can be overlooked are the altitude of the line and the temperature of the conductor. For instance, in the Northwest, altitude is a factor requiring consideration.

A practical approach to the problems of corona loss and radio influence naturally is to evaluate the results of experience from existing high-voltage lines; these can well serve as a valuable criterion or bench mark in projecting design to and in establishing operating standards for the higher transmission voltages. For example, 230-kv experience in a given region, duly evaluated and further supplemented by fundamental studies in the field and laboratory at 230-kv

Figure 1. Ambient and climatic conditions

and higher voltages, will provide a valuable basis in projecting transmission-line design in that region to higher voltages; that is, 288 kv or 345, or possibly 360 or 380 kv, as the case and economics may require.

The results of research studies and experience at Chevilly, France, in Sweden, on the Los Angeles 288-kv lines, from the special investigations in course in various quarters, and those now becoming available from the Tidd test project, are providing a more secure basis in the development of transmission-line design for the higher voltages and in arriving at the more economical solutions for long-distance power transmission.

Tables I and II and Figure 1 of this discussion illustrate the approach in estimating the performance of larger conductors "B" and "C" for operation at correspondingly higher transmission voltages, where conductor "A" serves as a bench mark or reference for 230 kv. The corona losses for the entire line (conductor "A") are determined by test over a sufficiently long period of time to establish an annual corona-loss distribution curve. Thus, the tests integrate the combined effects due to climate (rainfall, snow, sleet, and so forth), surrounding conditions, altitude, and other influencing factors present in the region and route traversed by the lines.[1, 2] Similar tests need be made, of course, with reference to radio-influence effects. The evaluation of radio influence in projecting transmission-line design to higher voltages is understandably much more difficult than corona losses. With the larger conductors this inherently is the case, because even small irregularities on the conductor proper, or rain or deposits, are conducive to concentrated streamer formation or discharges with resulting radio-influence effects of corresponding high levels resulting therefrom.

The corona-loss data presented in Tables I and II of the paper have been analyzed, consideration being given to the factors which influence corona loss, namely: a. the conductor and conductor arrangement; b. precipitation; c. altitude; d. temperature of air at conductor; e. spacing of conductors; and so forth. Two cases have been considered: one where precipitation corresponds to conditions in the East and altitude (profile of the line) does not exceed 1,000 feet; the other, where the average altitude is 2,000 feet and the rainfall 15 inches for one-half of the line and 40 inches for the other half.

In the light of these and similar analyses, the data presented in the Tidd Report indicate that:

1. On the basis of an annual corona loss of 5 to 6 kw per mile, a line designed and equipped with single 2.0-inch diameter steel-reinforced aluminum cable (ACSR) (expanded) conductors, spaced 40 to 45 feet, should be satisfactory for operation at 380 kv. The French, in their investigations at Chevilly, have found a 1.92-inch diameter ACSR conductor adequate for 380/-400 kv but not as favorable as a 2×1.04-inch bundle conductor spaced 16 inches.[3, 4]

2. On the same basis of corona loss, a 1.65-inch diameter ACSR conductor should be suitable for 345 kv.

3. In the Tidd Report, the 2×0.92-inch bundle conductor spaced 20 inches does not compare favorably to the 1.65-inch diameter conductors. This is due in part apparently to the choice in the spacing. Either a smaller spacing (less than 20 inches) or a larger diameter would have been more appropriate.

4. Finally, based on the statement in the Tidd Report that radio noise is the determining factor at the higher voltages, over and above corona-loss considerations, it then would appear that a conductor greater than 1.65 inches in diameter but less than 2.0 inches might be required for 345-kv operation.

In conclusion, a technique is rapidly in course of development which, when completed, should provide a more secure, straightforward, and more economically sound basis of transmission-line design at the higher voltages. Contributions such as the present one are providing valuable fundamental data in establishing this technique.

Table I. Annual Corona-Loss Distribution for "A" and "B" Conductors

Per Cent of Time	Corona-Loss Distribution for "A" Conductor at 230 Kv, Kilowatts Per Mile (Actual)	Corona-Loss Distribution for "B" Conductor at 287 Kv, Kilowatts Per Mile (Estimated)
0.8	11.6	27
7.7	8	18.6
20	4	9.3
8.5	2	4.7
63 (fair weather)	1.25	2.9
Average kilowatts per mile	2.45	5.70

Table II. Relative Operating Voltage as Determined from Geometric, Gradient and Stranding Factors of "A," "B," and "C" Conductors

$E_{L-L} \propto (r/n\ s/r)$ (Gradient Factor Stranding Factor)

Conductor	r/n	s/r	Gradient Factor	Stranding Factor	Relative Operating Voltage
"A"	3.50	1.00	0.80	0.80	230 kv
"B"	4.24	0.98	0.93	0.93	282 kv
"C"	5.76	0.947	0.95	0.95	382 kv

Engineering Staff (Anaconda Wire and Cable Company, Hastings-on-Hudson, N. Y.): The quantity of data which has been accumulated thus far in the Tidd project experiments is truly staggering. No interpretations or conclusions are attempted in this paper since, as frankly stated, no systematic analysis of any considerable quantity of the data has been made as yet. The sample data presented in the paper stimulates one's interest in the promised series of complete reports. Of particular interest is the authors' statement that single measurements of corona loss are misleading and that continuous, long-time tests are required to establish annual losses.

The general pattern of results appears consistent with data obtained by other investigators, as evidenced by these facts:

1. The long-time decrease of corona due to weathering has been reported, without exception, by all experimental investigators here and abroad.

2. The short-time surface effect is confirmed by Ailleret and Cahen.[1]

3. Automatic records of corona loss versus weather, similar to Figure 2 of the paper, were presented by the Germans[2,3] and by the French[1,4] and confirm the authors' findings.

4. The overwhelming importance of precipitation in corona loss is amply proved by the data presented. The Swiss[5] have done considerable work to appraise the individual effects of humidity, fog, rain, snow, and frost upon corona. They too found rain to be of paramount importance.

5. The consistent curves of corona loss versus rate of rainfall check well with similar curves by Cahen[6] of corona loss versus height of rain water. (It would be of interest to know the type of conductors, line spacing, and so forth, applying to curves in Figure 5 of the paper.)

However, one outstanding point of difference is noted. In the entire literature on bundle conductors it is accepted that bundles have not only higher corona starting voltage but also lower corona losses, for a given voltage, as compared with an equivalent single conductor. In every case, these results were based not only on calculations but confirmed by measurements by German, Swedish and French investigators.[1,2,3,4] Figures were published by Henning and Skagerlind[3] indicating that the ratio of operating voltages for equal corona loss on 2-conductor bundles and single conductors of the same diameter is approximately 1.4-to-1.

The 2×0.92-inch bundle conductor spaced 20 inches, referred to in Table I of the paper, means that the subconductors were spaced somewhat greater than the theoretically optimum spacing. If the subconductors are spaced too far apart, one simply adds up the corona losses of the individual (smaller) subconductors, which losses can be quite high. Ailleret and Pelissier[4] show that twin bundles with subconductors of 411 square millimeters (810,000 circular mils) give much lower losses than large single conductors (1.77- to 1.97-inch diameter), if the bundle

subconductors are spaced from 8 to 16 inches apart.

Referring to the Tidd tests, we appreciate that it is not possible to test all conductors simultaneously in order to obtain a direct comparison and that Tables I and II of the paper probably are not intended to offer such a comparison, but the very form in which the information is presented makes it inevitable that such comparison will be attempted by the uninitiated. Data on the effect of conductor size and construction upon corona are too meager to permit definite conclusions. Only these comparisons seem valid:

1.65-inch Heddernheim (HH), 3-phase, 45-foot spacing, versus 2.0-inch ACSR, 3-phase, 45-foot spacing.

1.65-inch ACSR, outer phase, versus 2.0-inch ACSR, outer phase.

No data are reported for the 2.0-inch type HH, 1.65-inch I beam, and bundle conductors for three and four conductors per phase.

Tables I and II of the paper indicate that the 1.65-inch HH conductor was measured 3-phase, the 1.65-inch ACSR phase-to-phase, the 2.0-inch ACSR both ways, and the bundle conductor only phase-to-phase. The spread of results as shown is not given in a form which would enable one to evaluate the conversion of single-phase measurements to 3-phase losses. If the standard deviation of each test conductor run were given it would help considerably. Both 2.0-inch ACSR conductor sets of values show as much difference from each other as do the other comparable conductors. This may be due to inherent inaccuracy of the conversion or to different spacing, although it is not clearly stated. Conversion of the corona losses of 1-phase measurements to 3-phase values is based on the assumption that the same electrical gradient gives rise to an equivalent corona current. To evaluate the field gradient for the conversion requires a knowledge of the ratio of the capacitance of the single-phase bundle conductor to its 3-phase operating capacitance. Since no data are given for capacitances, it is presumed that these were calculated and so used in the conversion formula.

We also wonder if some of the variations under normal dry conditions may be ascribed to variations in the electron density in free space about the conductor. Such electron density variations may be brought about by cosmic ray showers, sun spot activities, Aurora Borealis phenomena, magnetic storms, and the like.

M. Temoshok (General Electric Company, Schenectady, N. Y.): From dual conductor theory three factors tend to cause lower corona losses on dual conductors than on single conductors:

1. For equivalent areas of dual and single conductors, the maximum voltage gradients on the surface of the dual conductors is less than for the single conductors.[1]

2. Because of the relative location of the dual conductors, a varying gradient exists around the periphery of each conductor with the minimum gradient appreciably less than the maximum gradient.[1]

3. With conductors having the same surface gradient the losses tend to vary as the square of the radii.[2] First, let it be stipulated that the cross-sectional area per phase for dual and single conductors be equal, and second, that the surface voltage gradient be equal in each case. The corona loss of each dual conductor modified by the square of the ratio of conductor radii would have one-half the loss of the single conductors. But because of two conductors per phase, the losses in each case should be equal. But experimental data appear to indicate that small diameter conductors in general tend to have less loss than large diameter conductors when both have identical surface voltage gradients and have losses modified to a common conductor radius base.

Keeping areas per phase equal, instead of 1.65-inch diameter and 2.0-inch diameter single conductors, dual conductors of 1.17-inch diameter and 1.414-inch diameter respectively could be used with resulting lower corona losses. To attain equal losses the dual conductor diameters must be less than those just mentioned.

An interesting comparison of the results presented in Tables I and II of the paper may be made with the work presented in reference 13 of the paper. Based on the conductor outside diameters of Tables I and II, the ratio of areas of the single conductors (1.65-inch and 2.0-inch diameter) to the combined area of the dual conductors (0.92-inch diameter each) is 1.61 and 2.36 respectively. Investigators in reference 13 of the paper arrived at a conclusion indicating that if the ratio of areas was 1.65, the losses of the single and dual conductors would be approximately equal, depending on the spacing between the dual conductors. These relationships are borne out in this paper. The 20-inch spacing between dual conductors is fairly large, and if it could be decreased to 15–18 inches, even less corona loss should result.

Philip Sporn and **A. C. Monteith:** The authors appreciate the interest shown and value the comments of all the discussers. Questions are raised concerning the insufficiency of the data. A progress report by its very nature is limited in the completeness of the data presented. As mentioned in the paper, subsequent papers giving much greater detail will be presented. It is hoped that the future papers will answer in much more detail than is possible in a discussion of this nature the questions raised by the discussers.

The use of a 20-inch separation for the study of bundle conductors is questioned. Actually other separations also were tested and little difference in the results was observed. Mr. Temoshok in particular suggests that a separation of 15 to 18 inches instead of 20 inches would have resulted in less corona loss. Analytical studies made by a number of investigators have shown very little difference in loss for separations between 15 and 20 inches in a 2-conductor bundle. For two 1-inch conductors, Mr. Temoshok shows only a difference of 1.3 per cent in surface gradient for a change in separation from 15 to 20 inches. The final choice of separation between subconductors of a bundle should not be selected to obtain the minimum value of the maximum gradient around the periphery. On the basis of such additional factors as reduced reactance, sleet-loading, charging kilovolt-amperes and sticking of conductors resulting from short-circuit currents, a larger than optimum separation determined on the basis of corona loss only should be selected. A design should be chosen that balances these factors against increased loss and radio influence with increasing separation.

Power-System Planning in the City of Los Angeles

A. L. WILLIAMS
ASSOCIATE AIEE

E. L. KANOUSE
MEMBER AIEE

THE phenomenal past and continuing growth of the electrical industry and its transition from a luxury to a necessity for living, business, and industry make long-range planning imperative. While it may not seem as urgent, planning for the future expansion of a power system is fully as important as supplying the present load, and the responsibility it entails is probably even greater.

One responsibility of a system-planning group is to recommend a power-system arrangement that gives maximum reliability consistent with reasonable annual costs, that is capable of economical extension for load and community growth, and that can utilize current advances in equipment and methods, all without future costly reconstruction or excessive obsolescence. To meet this responsibility, it is necessary to have some idea of what the amount of community load growth may be, what its general characteristics will be, and where its various component parts will appear in the community to be served. Only with this knowledge can the system additions needed for immediate growth be made with assurance that these additions will continue to function as a proper part of tomorrow's system.

The Department of Water and Power of the City of Los Angeles has attempted to estimate the probable future load, and its distribution, from studies of population, land use, and feeder demand. With a reasonable estimate of future load and its probable location established, the problem of formulating a basic plan of system arrangement is simplified, and a suitable long-range program of expansion may be initiated. Periodic re-estimate of the basic quantities involved is desirable, as is a continuing study to insure that each addition of generating capacity, with its attendant transmission and distribution facilities, adheres to the long-range plan.

Electrical Load Demands of the City of Los Angeles

In 1924 the Department undertook a survey to determine the electrical power demands of the city by load classes and by geographical areas. The method used was essentially a field survey of land use by the various classes of load, coupled with an application of electrical load demands which are related to unit square miles of the load class. Similar surveys were made in 1934 and 1944 and have furnished very interesting information on trends in Los Angeles which can be utilized to advantage in making long-range forecasts for the city.

Field Survey of Land Use

The initial phase of each survey began in the field, and consisted of estimating the land use of 1/4-square-mile areas in terms of some 12 different load classifications. The work usually was done by driving through the various areas and estimating what percentage of that area was devoted to each of the various types of activities. When this was accomplished, the 16 maps making up a 4-square mile area were totalled by load classes, and the square miles devoted to each of the 12 classifications were tabulated. In this way the land use of each 4-square-mile area of the city was determined, and the initial phase of the survey was completed.

The land use of the entire city area as of 1944, comprising some 453 square miles, has been tabulated in Table I. This table was prepared by totalling the results of each 4-square-mile area, and gives considerable insight into the manner in which land is used in the community. While it is of course impractical to include here the results of the survey for each unit area, it should be remembered that these have been determined, and are available for considering the need for stations and lines in the various sections of the city.

Loading Value Determinations

The second phase of the survey involved the estimating of kilowatt demands of a square mile of each of the 12 load classifications. Such estimates were made by relating actual typical areas to the electrical demands on feeders serving these areas. Analysis of individual feeders sometimes made it possible to utilize actual meter readings, where it could be shown that a feeder served a well-defined load area of substantially one classification. It was soon apparent that for some classifications the economic character of the area influenced the electrical demands per square mile. In such cases two demand figures were used, referred to as "high"- or "low"-load density areas. The low loading applied to old or small homes, businesses, or districts, while larger secondary business districts and new homes might be put into the high-load density class.

Table II shows average loading values determined in each of the three surveys, expressed in feeder demand per square mile of the individual classes tabulated.

Feeder Demands by Load Classes and Areas

With the land use per-unit area of the city available from the survey, and with determinations at hand of the electrical loading values for each square mile of such

Paper 50-144, recommended by the AIEE System Engineering Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 15, 1950; made available for printing April 10, 1950.

A. L. Williams and E. L. Kanouse are both with the Department of Water and Power, The City of Los Angeles, Los Angeles, Calif.

Table I. 1944 Land Use, City of Los Angeles

Description	Square Miles	Per cent of Area
Single-family residences	78.5	17.42
Standard flats	21.0	4.65
Apartments, under 4 floors	1.7	0.37
Large apartments over 4 floors	0.1	0.03
Commercial, 2 floors or less	11.5	2.57
Heavy commercial, 4 floors or more	0.7	0.16
Wholesale or small industrial	1.2	0.26
Heavy industrial	2.4	0.53
Individual heavy industrial	7.3	1.61
Vacant	130.8	28.92
Vacant subdivided	64.8	14.31
Cultivated farm land	98.8	21.83
Miscellaneous: parks, schools, golf courses, and so forth	33.2	7.34
Total	452	100.00

land use, the final step in the analysis was simply one of multiplication. As an illustration, the kilowatt demands of the various load classifications as found in the most recent survey (1944) have been totalized and tabulated in Table III. It is of interest to note that the total value of 733,347 kw of feeder demand, when corrected for diversity back to the central receiving stations, checked within 18,000 kw of the metered receiving-station simultaneous-peak output in 1944. This is a 3-per cent error, and was on the low side.

Long-Range Load Forecasting

The results of these three surveys, conducted over a 20-year period, were most helpful in indicating trends for current long-range load forecasting work.

On the premise that the electrical demands of a metropolitan area are almost wholly dependent on two factors—population, and the activities of that population, or land-use—trends in these factors were analyzed for the metropolitan area.

Population Estimates

If population is estimated on the basis of trend curves alone, there is no limit to the ultimate value that may be assumed. In most areas, however, there will be found some limiting factor that can be used to determine a possible ceiling. In the semiarid coastal plain on which Los Angeles is situated, it appears to be water supply. After a careful analysis of water available to the metropolitan area from the Owens Valley and Colorado River aqueducts and from local pumping sources, a possible future population for the area was assumed at 6,250,000. It must be recognized that ample opportunity will be afforded in the coming decades to revise that figure if other factors, unknown or discounted today, later show such revision to be warranted. The population of 6,250,000 was established on a metropolitan area basis in order to obtain the statistical advantages of working with larger quantities and to eliminate the troublesome problem of dealing with irregularly-shaped city boundaries.

In order to estimate the population in the city area only, reference was made to past trends and census data with respect to persons living within and outside of the city. Figure 1 shows the trends indicated by past census data, and also shows the assumed extensions of these trends to establish a basis for determining the probable future city population. This study indicates that the population of the city proper may be approximately 3,850,000 when the population for the metropolitan area reaches 6,250,000. This represents an increase of approximately 1,850,000 over the city's estimated 1949 population of 2,000,000.

Housing Requirements

Studies of the living habits of the people in the metropolitan area gave some indication of the possible housing necessary to supply the population, expressed in terms of single-family or multiple-dwelling units. Analysis of past trends in housing indicated that Southern Californians prefer individual homes, more than 50 per cent of the population being housed in single-family dwellings in 1944. It was recognized, however, that industrialization of the area will bring to bear economic factors which will force a somewhat larger percentage of the people into multiple housing in the future. Federal Census Bureau housing statistics were utilized to determine the number of persons per occupied-dwelling unit of the various types, and values of per cent vacancy, in order to relate area requirements with the number of persons to be housed in each type of dwelling. Figure 2 shows in graphical form the answers obtained and the past trends from which they were extrapolated.

Table II. Average Loading Values Per Square Mile

Commercial and Industrial Land-Use Requirements

In like manner the trends in the commercial and industrial load classes, as related to population, may be utilized to gain some insight into the square miles of these categories required by an increasing number of people. In these cases reference was made to average values of other large metropolitan areas, adjusted for the individual characteristics of this particular Southern California area. The results of these studies are shown in Figures 3 and 4, the upward trend of the curve in Figure 4 reflecting to some extent the tendency of industrial concerns to include large parking areas for employees as a part of the plant.

Future Land Use, Los Angeles City

The total land-use requirements of the city, as determined by this type of reasoning and analysis, are shown summarized in Table IV. Data from each individual 4-square-mile area of the city has been summarized to produce this information. For this particular table it was of interest to separate the San Fernando Valley area of the city in view of the extremely rapid growth and development there. It should be noted that in order to care for a population of nearly 4,000,000 in the city proper, with housing as indicated, it was necessary to consider San Fernando Valley as housing approximately a third of that portion of the people living in single-family dwellings. This is not at all

Figure 1 (left). Estimated trends in population distribution in 900-square-mile metropolitan area

Figure 2 (right). Estimated trends in land use for residential load classification, metropolitan area

illogical, in view of the type of development, zoning ordinances, and so forth, prevalent in that district today.

Electrical Load Demands of the Various Classifications

The values of future electrical load demands per square mile for each type of land use, and for high- and low-loading densities, were assumed after a careful study of past trends, present and possible future saturation values of various types of electric utilization equipment, and probable new applications, increasing lighting intensities, and so forth. The average values of these assumed demands are tabulated in Table V.

The total feeder demand of the future city was estimated by obtaining the product of the square miles devoted to each of the various load classifications, and the applicable assumed feeder loading per square mile. Table VI shows the results obtained, with a total feeder demand of 2,780,000 kw resulting. It is of interest and importance to realize that this feeder demand, when present values of diversity factors and losses are utilized, represents a receiving station demand of 2,198,000 kw, a distributing station demand of 2,417,000 kw, and a required generation of 2,303,000 kw. These required generating capabilities are those which just meet the estimated requirements, and do not include the necessary additions essential for normal reserve capacity or for protection against the effects of depleted water conditions in periods of low river flows.

Summary

Electrical load surveys of the type outlined provide the information for the development of a basic power-system plan adequate for the future load requirements and capable of accomplishment through step-by-step construction processes. The segregation of the load requirements as to load classes enables the drawing of probable system load curves, the determination of kilowatt-hour requirements, and estimates of possible revenues. Furthermore, the unit area survey provides data for detailed study of the requirements of the receiving station, distributing station, and local feeder load areas.

Development of a Basic Power Plan

As a result of the 1924 electrical load survey, the Department developed a basic system plan for the then-estimated future load requirements of 1,250,000 kw. In formulating such a basic plan it was recognized that for a city covering more than 400 square miles and relying to a large extent on hydroelectric power developed in large blocks and transmitted over long distances, consideration must be given to methods of consolidating and distributing the power in the load area. The plan devised is illustrated in Figure 5.

This plan provided that the future load be distributed from not less than six receiving stations, each of a maximum capacity of 240,000 kw, and each to be supplied with a source of power approximately equal to the load distributed from that station. Every receiving station with its power source and its 34.5-kv distribution system was to be considered an isolated power system, and each such isolated power system was to be connected to a common bus, or belt circuits, through suitable reactors. The proper voltage for the belt circuits and receiving station primaries was determined to be 138 kv. Connections between receiving stations and their power sources were to be at the most economical voltage, and if transformation was required it was to be accomplished with autotransformers located at or near the receiving station and incorporated as a part of the transmission line.

Steam sources, where they constituted

a power source or stand-by, were to feed into the 34.5-kv bus of the receiving stations and were also to furnish reactive kilovolt-amperes in lieu of synchronous condensers at such stations. Studies on which this plan was based indicated that, with 8-per cent reactors (on a 100,000-kva base) between each 138-kv load and belt bus, this arrangement would limit maximum circuit breaker duties on the belt line busses to 4,000 megavolt-amperes; on the 138-kv load busses to 2,500 megavolt-amperes; 1,500 megavolt-amperes on the receiving station 34.5-kv busses; and 1,000 megavolt-amperes on the 34.5-kv bus at the distribution stations.

The advantages inherent in this plan are:

1. The limited capacity interconnection between systems reduces the necessity for duplicate transmission circuits to each system.

2. It may not be possible or economical to have the power development, and transmission circuits or power available, equal to the demand of its corresponding distribution system. The difference can be equalized by the other systems over the belt circuits.

3. Because of periods of low water, it may be desirable to have one or two steam-generating stations as reserve. The interconnection over the belt lines not only makes steam reserves available, but greatly reduces the total steam stand-by capacity required.

4. During periods of growth, the belt-line interconnections permit a receiving station to be established in advance of the power source for the station, the belt lines acting as a supply during the initial years.

5. Additional receiving stations may be given belt-line support either through looped-in lines between existing stations or through new lines tapped off from an existing receiving station bus.

This basic plan was adopted in 1926, when only three receiving stations existed, and when city-owned generating capacity totalled less than 120,000 kw. It is the plan toward which all construction since 1926 has been aimed, and with the exception of certain expedients resulting from construction work done before the plan existed, or from acquisition of some private utility properties, the original plan has been very closely followed. However, the growth of the city has not been uniform by geographical areas, and all six receiving stations were needed considerably in advance of the load development. The sixth receiving station was put in service in 1943, and the loads on several existing stations are rapidly approaching ultimate design capacity.

Considerations Indicating Need for Current Review of the Basic Plan

On completion of the 1944 load survey, with the clear indication it provided of the greatly increased growth expectancy of the city, and in view of the imminent need for expanding the existing receiving station system, it was realized that the basic plan should be reappraised to determine its adequacy for a power system with peak demands approximately twice those considered probable in 1926. Developments in the art of power generation and transmission during the past 24 years have had pronounced effects on the short-circuit duties imposed on circuit breakers, and the importance of these effects on the ratings of hundreds of switches in the subtransmission and distribution system could not be minimized. The more important of these developments that have affected the Department's power system are:

1. The use of higher speed circuit breakers requiring such circuit breakers to open the circuit higher on the current decrement curve.

2. Lower reactance hydroelectric generators.

3. Increased speed and lower subtransient reactance of steam-electric generators.

4. Connection of steam generation sources directly to the 138-kv bus instead of to the 34.5-kv system.

5. Use of 138-kv underground cable in belt circuits and transmission lines.

Relative economic advantages to be obtained with various hydroelectric-to-steam-electric ratios are on a somewhat different basis than that contemplated in 1926, and certain technological changes in the art warrant consideration because of their important effects on the economics to be obtained.

For all of these reasons it was deemed

Figure 5 (left). Basic power-system plan for serving 1,250-megawatt load from combined hydroelectric and steam generation

Figure 6 (right). Expanded basic plan for distributing future city load from combined hydroelectric and steam generation totaling 2,400 megawatts

desirable to re-evaluate the basic plan, particularly since the load study data furnished indication of the approximate location of the future load increases.

The Basic Plan Applied to a 2,400-Megawatt Power System

In order to determine the possible limitations of the basic plan when applied to a power system nearly double the size originally contemplated, an a-c network analyzer study was made of an assumed 2,400-megawatt system constructed in accordance with the basic plan. By this means reliability, flexibility, voltage regulation, reactive kilovolt-ampere requirements, and short-circuit duties were determined and evaluated, and many operating problems were posed and answered.

In building up the assumed power system for such a check on operation, the following four broad principles were followed:

1. The system under study was made adequate to care for the presently estimated future demands of the City of Los Angeles, having a generating capability of approximately 2,400 megawatts, including approximately 250 megawatts of spinning reserve.
2. The study was made directly applicable to the existing power system by adding receiving stations, belt-line connections, and power sources, in accordance with the principles of the basic plan. Such additions were made with the results of the load study trends at hand, showing the probable location of future load growth.
3. For purposes of comparison, the system being checked had some new receiving stations connected to the present system by lines tapped off receiving station busses, and some stations connected by looping into the belt circuits; and steam plant power was fed into some stations at 34.5 kv and into others at 138 kv.
4. Hydroelectric power or steam-electric power was assumed as power sources for the various new receiving stations, in order to determine the various electrical requirements accompanying the use of each.

The resulting assumed power system is shown in 1-line diagram form in Figure 6. The receiving stations were assumed located geographically at the centers of the load areas served, and in developing the impedance diagrams of the transmission system a realistic view was taken of the probability of underground or overhead construction being used for the various connections.

Dozens of power-flow studies were made of the power system shown schematically in Figure 6, under normal, single-contingency, and multiple-contingency conditions of operation. The results of the studies clearly indicated the basic plan to be sound, to contain reliability and flexibility elements highly prized by the operating engineers, and to be capable of application to a very large power system. However, short-circuit duties were found to be excessive, amounting to 5,000 megavolt-amperes or more on the belt-line side of the bus reactors at several of the stations. This was true even though reactor sizes were increased from eight to ten per cent in each of the 138-kv busses at every receiving station.

It was recognized that circuit breakers could be built to meet these requirements, but the use of such circuit breakers would require eventual replacement of nearly all existing 138-kv circuit breakers. In addition, the hundreds of circuit breakers in the 34.5-kv distribution system also would require replacement if the switch duties on the high side of the receiving station banks were allowed to exceed the limiting values assumed for the basic plan. These low-voltage circuit breakers have been purchased to date in accordance with those values set forth in the section on Development of a Basic Power Plan, and in many instances space would not permit larger circuit breakers to be

installed without costly reconstruction of existing stations.

Modification of the Basic Plan

After due consideration of the results discussed previously, and on analysis of the fault-current contributions from the various sources of energy available to the belt-line busses, a simple expedient was found which not only made remarkable reductions in the short-circuit duty on the belt-line circuit breakers at every station, but actually reduced the capital investment represented in the power-system plan as studied. This expedient was to omit half of the circuit breakers in the belt-line connections at each station, tying each belt line to only one of the two busses.

The single-line diagram of Figure 7 shows the connections resulting, and a comparison of 3-phase short-circuit duties obtained with the double-bus and single-bus method of operation is shown in Table VII.

This remarkable reduction of belt-line short-circuit duties is accomplished without undue sacrifices in flexibility or reliability. It is obvious that under normal conditions the removal of one circuit breaker from each of the four line positions at a receiving station has no electrical effect on the operation. However, if a fault occurs on a belt-line bus, the short-circuit current is very greatly reduced because the two current-limiting reactors at the station are no longer in parallel.

The connections indicated in Figure 7 can be simplified by presentation as in Figure 8. Extensive network analyzer power-flow studies showed the plan to have completely satisfactory flexibility and reliability characteristics, and there is indication that, from a short-circuit duty standpoint, the plan may be capable of still further extension. It is quite apparent that the 3,500,000-kva interrupting-duty circuit breakers being purchased for the present needs of the power system can continue to be utilized on the greatly expanded system.

The Los Angeles 1950 Power System

The extent to which the basic plan has been followed to date is indicated by Figure 9, which shows schematically the present power system of the Department of Water and Power. Reference to this diagram will show how effective use has been made of the belt lines to equalize power sources and load demands, to provide for stations having no power source of their own, and to make steam stand-by available to all of the receiving station systems. Stations *A*, *E*, and *F* have been equipped with 115-kv belt-line connections as an expedient arising out of: 1. the use of a section of the original San Francisquito transmission lines as part of the belt system; and 2. the acquisition of certain Los Angeles Gas and Electric Company properties, including the Seal Beach Steam Plant and its associated 115-kv transmission lines.

Although the diagram of Figure 9 is a schematic 1-line drawing of the Department's present power-system connections, it has been drawn to represent approximately the geographical arrangement of the several stations. A distance of 33-line miles separates Receiving Station *E*, at the north of the city in the San Fernando Valley, and Receiving Station *C* at the south in the harbor area. The air-line distance between Stations *D* and *F* is 4.8 miles. At the present time the entire area of the city, comprising 452 square miles, is served from the 34.5-kv distribution systems fed from the six receiving stations shown. It will be apparent that the backbone of the basic plan has been constructed, and that the future load growth of the city can be served from additional stations, constructed to augment the existing system and connected to it in either of the two possible ways permitted by the plan. The results of the study of the expanded system offer reasonable assurance that operation will be highly satisfactory and that 3-phase short-circuit duties on the various circuit breakers will not exceed the ratings of most existing circuit breakers or those presently being purchased.

No zero-phase sequence network was developed for the expanded power system studied, and phase-to-ground fault duties were not investigated. However, studies of single-phase-to-ground fault duties on the existing system have shown

Figure 8. Double-bus, single-circuit-breaker receiving station connections

them to be considerably higher in some locations than the corresponding 3-phase duties. This condition has resulted from the practice of employing literally solid-grounded neutral connections. As the system is expanded, a continuation of the practice would undoubtedly increase circuit-breaker short-circuit duties to values above those tabulated in Table VII. It was recognized that the single-phase-to-ground short-circuit duties could be reduced by increasing either the positive-sequence impedance or the zero-sequence impedance. However, the positive-sequence impedance is the one through which power flows from the source to the load, and any increases in this quantity beyond those absolutely necessary for the control of 3-phase fault currents are detrimental to normal system operation. The zero-sequence impedance is that impedance offered to the flow of fault current in the system neutrals, and plays no part in the normal system operation, becoming a factor only under unbalanced conditions arising out of system trouble. Three-phase duties having been controlled satisfactorily by means of the connections employed, it was believed desirable to limit phase-to-ground fault currents by inserting impedance in the neutral connections.

Table VIII. Zero-to-Positive-Sequence Reactance Ratios

Station	Bus	Condition A*	Condition B**
Receiving Station A	34.5 kv	0.73	
	110 kv	1.56	
Receiving Station B	34.5 kv	0.90	1.25
	132 kv	0.67	1.26
Receiving Station C	34.5 kv	0.97	1.79
	132 kv	1.14	1.31
Receiving Station D	34.5 kv	1.04	1.25
	132 kv	0.88	1.05
Receiving Station E	34.5 kv	1.09	1.35
	132 kv	0.74	1.07
Receiving Station F	34.5 kv	0.87	1.22
	132 kv	0.75	1.12

*Condition A: Maximum fault current
**Condition B: Maximum neutral reactor voltage.

The insertion of impedance in system neutrals results in a voltage drop across that impedance under fault conditions, the magnitude of such drop depending on the ratio of zero-to-positive-sequence reactance. This ratio was determined on the a-c calculating board for two conditions: A. for conditions producing maximum fault current; and B. for conditions producing maximum neutral reactor voltage. Maximum fault current will usually occur with all transformer banks in service, while maximum neutral reactor voltage will be obtained with some of the bank capacity disconnected. Table VIII shows the ratios found on the power system represented by Figure 9, except that double circuit-breaker operation of the belt-line busses was assumed. Neutral reactors of five per cent (100,000-kva base) were used in most of the receiving station load bank neutrals, both high and low sides, and on the Boulder Dam auto-transformer banks at the line terminals.

It should be noted that the ratios ex-

Table IX. Maximum Voltage across Neutral Reactors

Station	Banks	Volts
Receiving Station B	Boulder Dam	16,000
	132-kv load	10,300
	34.5-kv load	6,230
	Boulder Dam tertiary	2,820
Receiving Station C	132-kv load	17,150
	34.5-kv load	5,840
Receiving Station D	132-kv load	12,350
	34.5-kv load	6,250
Receiving Station E	Boulder Dam	14,900
	132-kv load	12,000
	34.5-kv load	6,350
	Boulder Dam tertiary	2,610
Receiving Station F	132-kv load	12,800
	34.5-kv load	6,000

Figure 9. Present power-system connections

isting under condition B, giving maximum neutral reactor voltage, are well below 2.0 in all instances. In view of the tentative designation of 3.0 as the maximum ratio for which the term "solidly-grounded system" applies, this is indication that the use of neutral reactors to the extent indicated will not produce excessive voltages. To verify the indication given by this means, board measurements were made of the maximum voltages existing across the neutral reactors at the various stations under fault conditions. These are tabulated in Table IX.

Since the Department's transformers have all been purchased with insulation, on the grounded ends of the windings, tested for more than twice the maximum voltage possible with the neutral reactors indicated, there is no doubt but that neutral reactors may be safely utilized. The studies outlined above have indicated no hazards in employing this method for reducing short-circuit duties, and the advantages are numerous. In addition to the reduction of short-circuit duty which it accomplishes, impedance in the neutral connections is favorable to system stability under certain types of faults.

Conclusions

1. Land-use surveys provide basic information necessary for forecasting with considerable assurance the amount, character, and location of future electrical load growth. With these three growth factors determined, adequate plans may be made for meeting future generation, transmission, and distribution requirements.

2. Such land-use surveys, made at suitable and regular intervals, provide a continuing check of load growth forecasts and enable any required modification of the basic transmission and distribution plan to be made in sufficient time to avoid construction inapplicable to the ultimate system, and to best utilize existing plant without unnecessary obsolescence.

3. Power-system connections can be devised whereby numerous large power sources can be consolidated in a single load area without imposing excessive 3-phase short-circuit interrupting-duty requirements on the system circuit breakers. Series reactors in such system connections may be applied in a manner permitting them to function as current limiters during periods of short circuit without introducing serious voltage drops or energy losses during normal or contingency operation.

4. Where 3-phase short-circuit interrupting duties are maintained at nominal levels, the use of neutral reactors provides a suitable method for the control of single-phase fault currents.

Discussion

Berton S. Rice (Niagara Mohawk Power Corporation, Buffalo, N. Y.): This paper presents a very logical and apparently new method for determining the power system requirements for a large city, thus enabling the system planners to more adequately meet the needs for future growth.

In areas having heavy industrial loads such as electrolytic processes and rolling mills, it might be necessary to make surveys oftener than every ten years. It will be interesting to see where the results of a 1954 survey will fall in relation to the forecasts indicated in this paper.

The authors are to be complimented on their logical approach to what, at its best, is a difficult problem. The methods and ideas set forth can be easily adapted to any other city or to a combined metropolitan and rural area system.

W. A. Morgan (Bureau of Reclamation, Denver, Colo.): I would like to raise the question of whether it is safe to base an estimate of power use on a fixed population of 6,225,000 people in a location such as Southern California with its ever-increasing population. Apparently this figure is based primarily on available water supply that is anticipated in the future as being the limiting factor.

I do not feel that we should accept such a limit. Engineers will solve this problem of water limitation in some way, if there is a sufficient demand for it.

There is also the possibility that, as more people live in Los Angeles, the high percentage of single-family dwellings will be reduced, which would allow a denser population and larger use of power. In addition, it is likely that the use of power per capita

may be greater in the future than was assumed.

This all leads up to the question I have for the authors. How is it planned to take care of the contingency of having to supply a load in the Los Angeles area substantially greater than that assumed in the paper? For example, say that 10,000,000 people instead of 6,225,000 people made their homes in Los Angeles in the future.

A. L. Williams and **E. L. Kanouse:** The authors appreciate comments made by Mr. Rice and Mr. Morgan, and are pleased at the indication of agreement with the load study method as a system planning tool.

Relative to comment by Mr. Rice, unusually heavy industrial loads to be served might well involve special study as to their connection. The Department's only experience with a load of this type resulted in its connection to the 138-kv system. Interim surveys of limited areas also have been made in connection with abnormal load growth experience requiring immediate addition of distribution station facilities.

Mr. Morgan's point relative to the use of a fixed population value is well taken. Our own recognition of this fact is indicated by the use of the 6,250,000 population value as a "future," rather than an "ultimate," figure. Although our detailed studies to date have been based primarily on the load requirements for the population value of 6,250,000, preliminary studies indicate that the transmission, receiving station, and belt-line connection plan described can be considerably expanded without exceeding our basic assumed limits for short-circuit duties. It is believed that the periodic survey of 10-year intervals provides sufficient time to properly modify system plans as may be required.

Relative to Mr. Morgan's comment on possible future increases of water supply, it is of interest that in our most recent load study the estimated population, on the basis of water supply, was also very close to the population limit that would be determined by utilization of available land under presently indicated habits of living, in particular the predominance in this area of single-family dwellings. Since the preference for single-family dwellings has been continuous throughout the growth of the Southern California area, it seems probable that population increases that cannot be accommodated in the load study area, without a reversal of this established trend, will locate in outlying districts where sufficient land is available for single-family dwellings. This assumption seems to be confirmed by the recent large increases in single family housing construction outside the load study area.

High-Voltage Rectifier Equipment and Control for Tube Testing

S. R. DURAND
MEMBER AIEE

THE testing of radio transmitting tubes of several hundred kilowatts output rating in the RCA-Victor Company Advanced Development Laboratory at Lancaster, Pa., has required the installation of mercury-arc rectifier equipment of higher rating and greater flexibility and voltage range than any other rectifier equipment for this type of service in the United States. To protect tubes undergoing tests, several electronic circuits have been developed for control of the rectifier under all types of operating conditions.

Requirements

Mercury-arc rectifier equipment for tube testing was needed to provide 2,000 kw at 12,000 d-c volts with two 6-phase rectifier units connected in parallel, and 2,000 kw at 24,000 d-c volts with the two units in series. With each connection, 12-phase rectification was desirable and could be obtained by effectively displacing the d-c side transformer windings 30 electrical degrees.

A wide range of voltage adjustment was also an important requirement. To obtain this, a step regulator connected between the power-line circuit breaker and the paralleled a-c side windings of the two rectifier transformers was specified for reducing the voltage over an 80-per cent range in 32 steps to a minimum value of 2,000 d-c volts. Phase control by means of grids in the mercury-arc rectifier units then would permit regulation to lower values or fine adjustment of voltage between steps of the regulator. The basic circuit of the rectifier equipment installation is shown in Figure 1.

When testing new designs of high-power transmitting tubes, it is desirable to apply d-c plate voltage at a low value and to increase it gradually during initial operation, and it is vitally important to interrupt power quickly when internal flashovers occur in the tubes. Because the per cent impedance of the step regulator and rectifier transformers increases at low-voltage operation, it was an essential requirement to provide sensitive protective circuits that would differentiate between normal and fault currents, regardless of the voltage applied to a tube.

Circuit-Breaker Protection

An important requirement for the a-c power circuit breaker was that a tripping control circuit be designed for instantaneous response when a preselected overload current value was reached, regardless of the a-c phase or the part of the sine wave in which the current first attained this value. The circuit breaker is a metal-enclosed air-blast type in which the intense cooling and turbulence produced in the arcing zone by the sudden expansion of compressed air causes extremely rapid deionization of the arc path and arc extinction at the first current zero. An electronic overload tripping circuit is provided to take advantage of this high-speed characteristic of the circuit breaker so as to keep the over-all time a minimum from the occurence of a fault until its interruption. The circuit is shown in Figure 2.

The air-blast circuit breaker, *52*, is equipped with two trip coils, one of which (not shown in the diagram) is operated in the normal manner from any one of three inverse-time overload relays, *51*, and a 48-volt battery. The other trip coil, *52T2* is actuated much more rapidly by release of the energy stored in a 50-microfarad capacitor. The charge in this capacitor normally is maintained from the low-voltage auxiliary supply circuit by means of a selenium rectifier. It is released by conduction of a thyratron tube when the control grid of this tube receives a positive triggering potential. This potential emanates from the fault current first produced in any one of the three a-c power-supply lines through current transformers connected to 1/2-ohm adjustable resistors, step-up transformers and cold-cathode discharge tubes. The potential applied to the control grid of the thyratron tube thus is determined by the discharge voltage level of the cold-cathode tubes so that a positive triggering potential of definite magnitude is obtained regardless of the direction or phase in which the overload current first reaches fault value in the a-c power-supply lines. Adjustment to cause tripping of the circuit breaker at any desired overload setting is made by means of contacts on the 1/2-ohm resistors and a positive bias applied to the anodes of the cold-cathode tubes.

Step-Regulator Voltage Control

The transformer windings of each phase of the Y-connected 3-phase regulator are designed with two coils so that both a buck and a boost connection can be made between them by means of the operating mechanism. This contact-making mechanism employs the principle of compressing and releasing springs to obtain a quick make-and-break action when moving between the contact sectors of each position under load. The two moving contacts of each phase are connected to a center-tapped reactor which limits the circulating current when these contacts overlap between two tapped positions. This enables the contact mechanism to be designed so that the circuit is never broken.

The contact positions cover an effec-

Paper 50-145, recommended by the AIEE Electronic Power Converters Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 13, 1950; made available for printing April 11, 1950.

S. R. DURAND is with the Allis-Chalmers Manufacturing Company, San Francisco, Calif.

Figure 1. Basic power circuit of rectifier installation

tive range of 16 taps on the series coil of each phase while it is connected in bucking relationship with the magnetizing coil. At the midvoltage position, a reversing switch operates so that the same taps of the series coil may be utilized while it is connected in boosting relationship, thus economizing on the construction of both the electrical and mechanical parts. Actually, only eight taps are brought out from the series windings and connected to eight contact sectors, each alternate position of the stepping mechanism functioning to interconnect two adjacent contact sectors through small center-tapped reactor so as to obtain a voltage halfway between them. With 32 effective positions each of $2^3/_4$ per cent, the voltage can be varied by means of the regulator in 320-volt steps.

Transformer Connections

The transformers for each 1,000-kw rectifier can be used to provide several different types of d-c side circuit connections such as 6-phase diametrical, 3-phase Y series or parallel, 3-phase delta series or parallel, and 3-phase zigzag. All these circuits can be set up readily because each end of the six d-c side phase windings are connected to high-voltage single-pole, double-throw wall switches, and jumpers are provided for interconnections between the switches.

One transformer is equipped with a delta a-c side winding and the other with a Y and tertiary winding so that equivalent 12-phase rectification will be obtained with normal 6-phase operation of each rectifier in either the parallel or series output d-c connection. The transformers, step regulator, and metal-enclosed switchgear are located outdoors in a fenced-in section adjacent to the laboratory building, and the rectifiers, filters, wall switches, and control equipment are installed within the building.

Rectifier Units

Each mercury pool rectifier unit is a 6-phase pump-evacuated steel-tank type mounted on an insulated frame which also includes the control cubicle and a water-to-water heat exchanger. In order to insulate the water supply circuit, cooling water is run through a porcelain insulating coil mounted adjacent to each frame. It also is essential to insulate the 3-phase 230-volt auxiliary power supply for the rectifiers and control equipment. This is accomplished by insulating transformers designed for 95-kv dielectric test between windings.

Each anode of the mercury-arc rectifier units is equipped with two graphite grids. Each grid has a terminal connection so that separate phase-control circuits may be used for the upper and lower grids to control the regulation of d-c output voltage. A phase shifter is mounted in each control cubicle and each phase shifter is driven through an insulating shaft by a small geared motor mounted on a front grounded-steel control panel. Instruments located in the control cubicle at high voltage above ground potential may be viewed through a glass window in the front steel panel.

Phase-Control Voltage Regulation

Another interesting electronic control scheme employed in this installation is a phase-control circuit for d-c output rectifier voltage regulation. This circuit uses thyratron tubes for applying positive impulse potentials to the mercury-arc rectifier grids, and for setting a small advance angle to the potentials applied to the lower ionizing grids with respect to the potentials applied to the upper control grids. The essential elements of this circuit are shown in Figure 3, the diagram being drawn to show the control-tube connections completed through current-limiting resistors to only one set of grids associated with one main anode of a rectifier unit. A negative biasing voltage with respect to the cathode of the mercury-arc rectifier is maintained continuously on all grids by means of a selenium rectifier equipped with output filter. Each upper and lower rectifier grid is permitted to become positive only by triggered voltage impulses from the thyratron tubes controlled (in phase relation to the potentials applied to the rectifier anodes) by means of the phase shifter previously mentioned. Steep wave-front impulse potentials are obtained by applying 60-cycle sine-wave voltages to the anodes of the control tubes 60 electrical degrees in advance of the filtered sine-wave voltages applied to the control-tube grids. The positive-impulse potentials impressed cyclically on the main rectifier grids in this manner offset the negative bias so that each pair of grids regulates the firing instant of its anode with accurate timing control.

Figure 2. Electronic trip circuit for circuit breaker

Figure 3. Phase-control voltage regulation circuit

A slight angle of advance is applied to each lower ionizing grid with respect to the associated upper control grid by means of a resistor inserted in the neutral lead of the grid transformer of the control tubes for the upper main grids. This causes the negative bias for the grids of these control tubes to be greater than that for the grids of the lower control tubes, and thus results in an angular delay in firing sequence of the order of one electrical degree. More accurate pickup and control of firing of the anodes of the main rectifier units is attained in this manner.

Regulation of the d-c output voltage of the rectifier units is controlled by operation of the geared motors driving the phase shifters to advance the relative angular setting to obtain higher values or to retard it to obtain lower values. The control is very flexible because it can be operated in conjunction with the step regulator for applying precise values of d-c plate voltage to transmitting tubes. Portable stands with instruments and multiconductor cable connections are provided so that complete starting and stopping control and voltage regulation can be set up at any place in the laboratory.

Differential Protection Circuit

Sensitive high-speed overload protective equipment is required to differentiate between normal and backfire fault currents that might be only slightly different in magnitude when operating at low voltage. This circuit differentiates between the a-c input and d-c output current so as to cause the circuit breaker to be tripped instantly should a backfire occur even at a relatively low voltage.

A rectified d-c current is obtained from the 3-phase a-c input side of each rectifier unit by means of current transformers, three center-tapped insulating transformers, and selenium rectifiers. A direct current in the main output circuit is obtained from a resistor of 1-kw heat dissipation rating inserted in the grounded side of the rectifier equipment, the loss in this resistor being insignificant in comparison to the output rating of the installation. A rheostat enables one direct-current to be adjusted in relation to the other in order to set the initial balance condition. The two currents are about equal and opposed to each other under normal loading of the rectifier equipment so that no current flows through the coil of a sensitive high-speed relay unless a backfire occurs. In this case the current values on the a-c and d-c sides will be radically different, and the relay will operate to cause the a-c circuit breaker to be tripped.

Arc Suppression

In addition to high-speed tripping of the main circuit breaker by means of the electronic overload circuit or the differential protection circuit, it also is possible with rectifier units of this type to utilize electronic circuits to prevent some of the main anodes from firing into a fault after it occurs. Thus, the anodes carrying current at the instant of a surge or overload will continue to carry the fault current until it is extinguished, but the other anodes that would normally conduct current in successive order can be prevented from firing into the fault.

When a flashover occurs in a tube undergoing test, the voltage across the tube will collapse instantly so that if a reactor is connected in series with the tube, nearly full voltage will appear accross the reactor. An auxiliary winding on the reactor insulated from the main winding for a high-insulation voltage level thus can be utilized to transmit an impulse-triggering voltage to electronic tubes. These tubes function to prevent ionization of the arc paths between the mercury pool and any anodes that are not carrying current in the main rectifier, and thus limit the magnitude and duration of a fault current. Other types of load fault detecting equipment also can be utilized to effect high-speed protection.

When circuits of this type are employed, it is essential to use electronic devices throughout to gain full advantage with respect to the extremely short time in which an air-blast circuit breaker can interrupt power. Because the fault-detecting equipment may be located in the circuit effectively at ground potential whereas the mercury cathodes of the rectifier units may be several thousand volts above ground, it is necessary to transmit impulse voltages through insulating transformers between the detecting and electronic-actuating devices.

By means of separate insulating-transformer windings and electronic-impulse control circuits, it is possible to restore power when desired by manual control or by a timing device. In some cases flashovers may reoccur instantly each time an attempt is made to automatically restore power, so that it is desirable to have a means of limiting the number of successive attempts to resume operation. This can be provided by use of a proportioning stepping relay. If only one or two steps are made and then normal operation is successfully reattained, the relay will eventually reset itself automatically to its initial position, but if the preset number of successive steps is completed due to inability to restore normal operation, the relay will cause the circuit breaker to be tripped to open the power-supply circuit.

If fault-responsive circuits are employed for arc suppression in the rectifier units, they must respond at a more sensitive setting and function at a lower value of current than that set for the electronic circuit for circuit-breaker tripping. Otherwise, the main air-blast circuit breaker always will be opened regardless of the

nature or magnitude of the existing fault.

Electronic-control and protective circuits provide some of the most useful and important features of this 2,000-kw rectifier installation which is essential for the development of new high-power radio-frequency tubes for radio and industrial applications. Mercury-pool rectifier units have proved to be reliable in performance and ideally suited for the diverse duty imposed on them in this type of testing service.

No Discussion

High-Voltage Ignitron Rectifiers

M. J. MULHERN
ASSOCIATE AIEE

THE development of new types of sealed ignitron tubes has made possible rectifier equipment which is capable of delivering high power at moderately high direct voltages. These tubes permit the design of high-voltage equipment which has the same reliability in operation as its low-voltage counterparts. The practically unlimited emission of the pool cathode, the long life of the tube, and the lack of moving parts are other characteristics of this equipment. These features bring to the high-voltage field the same power ratings, high efficiency, and high grade of performance that are found in the low-voltage rectifier equipment, which is used widely in general industrial service.

This paper discusses the circuits, design factors, and operating features of two high-voltage rectifiers. Each of the rectifiers described is a typical design for its rating. The first rectifier is designed to deliver 17,000 volts at a load of 2,500 kw, and uses 50-ampere sealed ignitron tubes. The other rectifier is designed to deliver 17,000 volts at a load of 7,500 kw and uses 150-ampere sealed ignitron tubes.

General Description of Equipment and Tubes

The general arrangement of the cubicles in each rectifier is indicated in Figure 1. The 6-phase double-way power circuit is used in both rectifiers. This power circuit permits mounting the ignitron tubes in pairs, together with their associated circuit components. The tubes which are paired conduct current during alternate half-cycles of the supply voltage. This type of mounting of the tubes and circuit components permits a unit-type of cubicle assembly, and results in a more simple mechanical arrangement and reduces floor space requirements. The two machines have similar electrical and mechanical design features. They differ mainly in physical size and weight.

The 2,500-kw rectifier consists of five cubicles, each of which is $2^1/_2$ feet wide and four feet deep. There are three tube cubicles, a control cubicle, and a d-c cubicle. A-c power is connected through bushings in the rear of the control cubicle, and d-c power is delivered through bushings extending from the side of the d-c cubicle. The 7,500-kw rectifier consists of four cubicles, each of which is six feet wide and five feet deep. There are three tube cubicles and a control cubicle. A-c power is connected through three bushings located in the top of each tube cubicle. D-c power is delivered through a bushing in the top of the control cubicle with one side of the d-c grounded.

Both rectifiers employ similar excitation systems.[2] The actual circuits differ slightly because of the different characteristics of the two ignitron tubes. These machines incorporate a water-to-water heat exchanger for removing the arc-losses from the tubes. The correct tube temperatures are maintained at any value of load by the temperature regulating controls. Electrical control circuits provide for operation of the rectifier auxiliaries and for proper starting and stopping sequence.

The 50-ampere sealed ignitron tube[2] which is used in the 2,500-kw rectifier is shown in Figure 2 and in the diagram of Figure 3. The over-all height of the tube, excluding the length of the anode lead, is 22 inches and the tube is $5^1/_2$ inches in diameter. It weighs approximately 25 pounds. The internal structure of this tube is similar to other types of sealed ignitrons except for the addition of the grids. The mercury pool cathode, ignitor, and excitation anode elements are the same as in the low-voltage tubes. Current flow is initiated by the ignitor and control grid voltages. The ignitor establishes the cathode spot and starts emission, while the control grid voltage determines the instant at which anode conduction begins. An important feature of this tube is the second grid located between the control grid and the anode. This is called the gradient grid[1] and effectively divides the anode-cathode space into two regions. Its purpose is to control the anode-cathode potential gradients during nonconducting periods and this construction results in a tube which will withstand much higher inverse and forward voltages. The baffle below the control grid structure serves to deflect mercury droplets away from the grid structure. It also aids in deionizing the grid-cathode space after current conduction ceases. This ignitron carries a continuous direct current rating of 50 amperes at 20,000 volts.

The 150-ampere sealed ignitron tube[1] which is used in the 7,500-kw rectifier is shown in Figure 4 and the diagram of Figure 5. The internal structure of this tube is similar to the 50-ampere ignitron except that it employs three grids, and it is much larger in size. It is 42 inches in over-all height, excluding the anode lead, and it is nine inches in diameter. It weighs approximately 100 pounds. From the cathode the grids are, first, the shield grid; next, the control grid; and then the gradient grid. The shield grid assists in deionizing the space near the control grid immediately after conduction. The other elements provide the same functions as in the smaller tube. The tube carries a continuous d-c rating of 150 amperes.

Both tubes are operated with control (and shield) grid voltages negative with respect to the cathode except during the conducting period. The gradient grids are operated at some intermediate value of the actual anode-to-cathode voltage, usually 50 to 65 per cent. Each ignitron

Paper 50-146, recommended by the AIEE Electronic Power Converters Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 16, 1950; made available for printing April 11, 1950.

M. J. Mulhern is with the General Electric Company, Schenectady, N. Y.

carries a momentary surge current rating approximately 30 times its continuous rated value.

Circuit

The power and excitation circuits are shown in Figure 6. The double-way power circuit delivers twice the direct voltage of a double-Y circuit for the same rectifier transformer secondary voltage. The circuit also requires only three secondary windings on the rectifier transformer and only three high-voltage a-c connections between the transformer and the tubes. The double-way connection results in better utilization of transformer capacity and requires less insulating material on the a-c side than other rectifier circuits.

The symmetry of the power circuit allows several possible circuit arrangements on the d-c side. The d-c busses may be ungrounded, or either bus may be grounded according to the particular installation requirements. The equipments shown in Figure 1 illustrate two possible arrangements. The 7,500-kw unit has a single d-c bushing with provision for internally grounding either the positive or the negative bus. The 2,500-kw unit is provided with two d-c bushings and an internal grounding switch. Either of the d-c busses may be grounded externally as required. The switch provides a safety precaution by grounding both d-c busses in order to discharge the external circuits which are connected to the rectifier before any cubicle doors are opened.

The surge filter shown in the circuit diagram provides a discharge path for the stored energy in the rectifier transformer secondary windings during tube commutation intervals. The filter is a 3-phase

Figure 3 (below). Construction of 50-ampere sealed ignitron tube

Figure 4 (left). 150-ampere sealed ignitron tube for use in 20,000-volt circuits

Figure 3 (right). Construction of 150-ampere sealed ignitron tube

resistance capacitance network with circuit constants chosen for critical damping. The inductance corresponds to the commutating reactance at the transformer secondary terminals. The value of inductance depends upon the per-unit reactance of the transformer and the per-unit reactance of the power system. The surge filter limits the transient voltages which are produced by the commutation of the load current from tube to tube. These voltages, if undamped, would be sufficiently high to damage the transformer winding insulation, particularly when the rectifier is operated with large amounts of phase retard. The combined resistance losses are approximately 1 per cent of the rectifier rating. This, however, results in a power loss of 3.5 kw per resistor assembly in the 2,500-kw machine. The resistor assembly is, therefore, rather large since this is an appreciable wattage.

The excitation system provides ignitor, excitation anode, and grid voltages for each of the tubes. The circuit components employed are all static devices which have long life and require low maintenance. The excitation system also includes a phase shifting network which

Figure 6. High-voltage rectifier circuit diagram

provides continuous control of the phase of all of the tube excitation voltages. Excitation power is derived from the auxiliary bus through a set of adjustable phase shifting transformers. These transformers energize the phase shifting network which delivers power to the excitation bus. All of the excitation circuits are supplied from this bus. The phase shifting network is capable of adjusting the phase of the excitation bus voltages over a range of 150 degrees and thus permits smooth control of the rectifier output from zero to full voltage. The phase shifting network provides a constant output voltage over the full phase shift range, resulting in constant circuit performance of the excitation system.

The insulating transformers shown in Figure 6 indicate the insulation line between the circuits at ground potential and those mounted at high potential. The ignitor firing circuits are located at ground potential, and the ignitor pulses are coupled to the ignitors through insulating transformers. The excitation anodes also are energized through insulating transformers which have their primaries connected to appropriate phases of the excitation bus. The grid circuits are energized from their respective excitation anodes. The grid voltages are obtained as a result of the switching action in the excitation anode circuit which occurs at the instant of ignitor firing. This circuit arrangement has two distinct advantages. The first is that the entire grid circuit may be mounted at high potential and the need for one set of insulating transformers is eliminated. The second is that the grid is automatically prevented from being energized with a positive voltage in the event of an ignitor misfire. This feature prevents damage to the ignitron tube which would occur if the grid were energized without a cathode-spot having been initiated. The gradient grids are energized by potential dividing resistances which supply a fraction of their respective anode-cathode voltages to them.

Design Factors

The circuit diagram, Figure 6, indicates the circuits associated with each pair of tubes. This natural grouping of circuit components is the basis of the tube cubicle design. The circuits within the tube cubicles fall into three groups, those at ground potential, and those associated with the cathode potential of each tube. The circuits connected to the cathode of one tube are made as a single assembly, insulated from the frame, and include the sealed ignitron mounting. The tube assemblies are mounted side by side in the cubicles in the 7,500-kw unit. The smaller size and weight of the 50-ampere ignitron permits mounting the assemblies one above the other in the 2,500-kw unit. The excitation insulating transformers, ignitor firing circuits, and water pipe headers are mounted on the floor of the cubicles in both rectifiers. The internal arrangement of the two types of tube cubicle assemblies is shown by the diagrams of Figures 7 and 8. The grid circuits are mounted in fully shielded boxes

Figure 7. Tube cubicle assembly for 2,500-kw high-voltage rectifier

Figure 8. Tube cubicle assembly for 7,500-kw high-voltage rectifier

Figure 9. Front view of 17,000-volt rectifier rated 2,500 kw and operating from 3-phase 13.8-kv supply

which minimize the transient voltages that would otherwise appear at the ignitron grids. The water jackets of the sealed ignitrons must be insulated from the grounded cooling system. This is provided by an insulating water column that connects the tubes to the water pipe headers. Distilled water of high resistivity is used in a closed, recirculating system. The water column is made of 30-foot lengths of neoprene hose, which is wound in a flat spiral and mounted adjacent to the tube mountings. Electrolytic targets are provided at each end of each hose to protect the fittings from electrolysis. The magnitude of the electrolytic current which flows will be 250 to 500 microamperes, depending upon the condition of the cooling water. The inlet and outlet hoses are wound together in one assembly in the 7,500-kw machine, and they are mounted in the insulating space to the right of the tube mountings. The inlet and outlet hoses are wound separately in the 2,500-kw machine and are mounted in the insulating spaces on either side of the tube mounting. The hoses are visible in Figure 9.

The cubicles in both machines have doors both front and rear. This affords complete accessibility to the tubes and excitation circuits. The grid boxes also are equipped with doors in the rear, so that these circuits may be checked without removing the tubes or their water connections.

The excitation insulating transformers have dual secondaries with internal shields between the windings. The switching action of the ignitrons causes their cathode potentials to suddenly shift, tending to induce high transient voltages across the transformer windings. The shields prevent the transient voltages from appearing across the windings and from being transmitted to other circuits.

The temperature of the sealed ignitron tubes has a direct bearing on the performance of the rectifier.[1,3] The tubes are designed for operation at water temperatures of 30 to 60 degrees centigrade. Operation at temperatures outside this range would result in higher arc-drop voltage, or loss of current carrying capacity, or frequent arc-back. The temperature regulating equipment in these rectifiers maintains the cooling water temperature between 35 and 45 degrees centigrade and automatically corrects itself for changes in ambient temperature. Correction of the temperature of the recirculated cooling water is made by adjusting the flow on the raw water side of the heat exchanger. Water heaters are provided so that the tubes may be quickly brought to operating temperature when starting. The temperature regulating equipment circulates 18 gallons of coolant per minute in the 2,500-kw machine, and requires ten gallons of raw water per minute at rated load. The corresponding flows for the 7,500-kw machine are 30 and 10 gallons per minute respectively.

Anode heaters are provided in order to prevent condensation of mercury in the anode region of the tube. The heaters maintain the anode seal and structure at a higher temperature than the adjacent parts of the tube. The heaters are enclosed in an insulated assembly which fits over the top of the tubes in the 7,500-kw unit. Heater power is supplied through the excitation insulating transformers. The heaters in the 2,500-kw unit are mounted on the tube cubicle doors in reflectors. The anode seals of the ignitrons have individual reflectors to distribute the heat uniformly. The heaters are energized at ground potential and, therefore,

permit the use of a smaller size of insulating transformer in the 2,500-kw rectifier.

Key operated door interlocks are provided on all cubicles which enclose high voltage a-c and d-c busses and tubes. A mechanical key sequence is provided which requires that all a-c switchgear and d-c switches be operated to a de-energized position and locked, before any high-voltage cubicle doors can be unlocked and opened. Additional electrical interlocks in the doors control the excitation system and the rectifier auxiliaries.

Operating Features

The control of the direct voltage output of the rectifier is obtained by adjusting the phase of the ignitor pulse. The phase of the ignitor pulse and the other ignitron excitation voltages is controlled by the phase shifting network. A direct current signal applied to the saturable reactors in the network is the means of control. This current may be obtained from a small d-c source and adjusted manually with a rheostat. This would provide manual control of the voltage. The control current may be obtained from a voltage regulator instead, and thus provide automatic regulation of the direct voltage.[6] The network provides a continuous function and the direct voltage output of the rectifier may be adjusted from maximum to zero.

An important feature of the ignitron tubes is their ability to rapidly interrupt the load current. The conduction in any one of the ignitrons will cease after the first current zero if the ignitor impulse is removed. The tubes will then "hold off" and prevent current flow until the ignitor impulse is again restored. The permissive action of the grid circuit is useful under these conditions, since the absence of a cathode-spot results in a negative voltage being impressed on the grid. The simplest means of interrupting the ignitor pulses is to short circuit the primary windings of the ignitor insulating transformers with a set of high-speed relay contacts. This relatively simple means of arc-suppression results in both ignitor blocking and grid blocking of the tubes to prevent conduction. This additional control feature of the tubes may be utilized as part of a control sequence for the rectifier load, or it may be used to interrupt fault currents.

Rectifier Operation and Application

The protection of this equipment against faults in the power circuit[4,7] is a problem which must be considered in its application. The use of ignitron arc-suppression[10] in addition to a power circuit breaker for backup protection affords the best combination for this type of equipment. The duty on the power circuit breaker will be reduced when arc-suppression is employed because the circuit breaker will not have to operate each time that a fault occurs. The arc-suppression feature also may be used to interrupt the d-c power for values of current less than the rectifier ratings, but which may be overloads for a section of the load.

Some faults which may arise[7,8] are, loss of control in an ignitron; faults in the d-c load circuit; faults in the rectifier transformer windings; and failure of high-voltage circuit components. It should be noted that very few failures in the ignitrons will result in sustained fault currents on the power system. The ability of the ignitron to recover after a fault is generally good, and permanent damage to the tubes or equipment is not likely.

The load regulation characteristic of the rectifier is a straight line in these machines. The maximum voltage drop from no load to full load depends solely upon the reactances of the rectifier transformer and the power system feeder. This regulation characteristic may be made flat over the load range by using a voltage regulator which will supply the control current to the phase shifting network.

There are some applications in which the poor direct voltage waveform of a rectifier operated at large phase retard cannot be used. In these cases, a regulating autotransformer is connected ahead of the rectifier transformer and it is used to raise and lower the supply voltage. Large changes in the direct voltage output are obtained in this manner, and phase control of the rectifier can then be used for small voltage changes and for regulating the direct voltage. These transformers are sometimes arranged to provide for tap changing under load.

A relay control system is usually incorporated in these equipments to insure that the rectifier auxiliaries are operated in proper sequence when starting and stopping the rectifier. The usual criterion for this sequence is that the tubes are not allowed to carry load unless they are at operating temperature. The tubes also are never operated with the anode heaters de-energized.

The operating features of this rectifier equipment make it suitable for many applications in the moderate voltage field. Some of these are as power supplies for radio transmitters, or for particle accelerators, or for high-voltage testing. Another important application is in their use as frequency changers in power systems.[5] These rectifiers incorporate the same features of long life, reliability, low maintenance, and easy accessibility as are found in the standard low-voltage industrial class of rectifier.

Synopsis: A general analysis of basic types of magnetic amplifiers without and with feedback is presented in dimensionless form. The use of a simplified approximation of the normal magnetization curve with a hyperbolic sine function permits a comparatively simple treatment of a most comprehensive nature on a purely analytical basis. General dimensionless characteristics are obtained which apply, without need for further calculations, to any kind of design specifications and to any core material of not too abruptly varying incremental permeability. Thus the influence of factors of design and materials on the performance is made evident. This approach also yields a practical method of accounting for the simultaneous conduction of the feedback rectifiers (commutation) in terms of a correction factor which is applied to the feedback ratio. Numerical values of this correction factor are calculated for some significant instances.

Introduction

In a recent study[1] an analysis has been presented for the determination of the steady-state characteristics of magnetic amplifiers in terms of data of design. The method is to apply Kirchhoff's and Faraday's laws to the electric circuits of the amplifier and to use Ampere's law to relate the magnetic field intensities and currents, expressing the empirical relationship between field intensities and flux densities by means of some convenient analytical expressions.

The procedure is facilitated by the use of simplifying assumptions: leakage fluxes, hysteresis, and eddy currents are neglected. The core fluxes are assumed to vary sinusoidally in time. Rectifiers as used in feedback amplifiers are assumed to have infinite resistance in the reverse direction and a constant small resistance in the forward direction.

When the normal magnetization curve of the core material can be approximated by a power series with a limited number of terms, or by hyperbolic functions, the method applied to the basic amplifiers of Figure 1 yields comparatively simple expressions for the instantaneous values of currents in the various amplifier circuits.[1,2,3] These expressions are in terms of the direct component B_0 and the crest of the alternating component B_{max} of flux density in the cores, and are checked quite well by experimental results. If for instance, the normal magnetization curve is approximated by a representation of the type $H = U \sinh uB$, $H = U \sinh uB + vB$, or the sum of two sinh terms, the currents are expressed in the form of harmonic series whose coefficients are modified Bessel functions for which tabulations are available.[4] Thus characteristic curves expressing output currents (rms or also rectified average values) in terms of the direct component of signal current and of the sinusoidal voltage applied are obtained, which also agree very closely with experimental checks.

This agreement also is obtained for feedback amplifiers, as the analysis[1] expresses accurately the differences in wave form of the output and feedback currents, which appear in portions of the cycle during which all of the feedback rectifiers conduct simultaneously. The time average value of feedback currents is accordingly increased, with effects which are particularly pronounced for instance when a forcing resistor is used in series with the signal circuit in order to improve the speed of response.

It is the purpose of this paper to elaborate further upon the findings of the previous analysis. The results are presented in the form of general dimensionless characteristics, that can be used directly for the amplifiers of Figure 1 without need for calculations, other than the simple ones required to convert the dimensionless data to the actual values corresponding to any specific design and core material.

Dimensionless Curves

The full line curves shown in Figure 2 represent in general dimensionless form the relationship between the alternating voltage across the amplifier terminals and the rectified average value of load current for different values of the total time average magnetomotive force due to signal, bias, and feedback currents for any of the amplifiers of Figure 1.

The calculations from which these curves result are based on an approximation of the normal magnetization curve of the core with a simple hyperbolic sine function

$$H = U \sinh uB$$

and they are intended to apply for those core materials (hypernik, hypersil, and similar improved transformer steel alloys) for which the simplifying assumptions already mentioned are valid.

This function may yield somewhat less close approximations to the experimental magnetization curve than those obtainable with some of those used in reference 1. However, the simplified approximation chosen is advantageous as it allows for a comparatively simple dimensionless treatment of a most general nature in pure analytical form. Samples of experimental checks, as shown later, indicate that the results are still satis-

Figure 1 (left). Typical magnetic amplifiers

Figure 3 (above). General dimensionless transfer characteristics of magnetic amplifiers

factory within the range of accuracy expected in problems of this nature.

The dimensionless ordinates of the curves of Figure 2 are

$$\mathcal{B}_m = uB_{max} = u\frac{E_m}{N}\frac{1}{\omega A} \tag{1}$$

where B_{max} (for example, in webers per square meter) is the crest of the component of the flux density in the core alternating at frequency f (cycles per second), E_m/N is the crest value of the corresponding volts per turn, $\omega = 2\pi f$ and A is the cross sectional area of one core (square meter). (For the amplifiers of Figures 1(A) and (C), $N = 2N_2$; for the amplifiers of Figures 1(B) and 1(D), $N = N_2$.)

The dimensionless abscissae are defined as

$$\mathcal{F}_L = \frac{1}{U}\frac{NI_{L\,ave}}{l} \tag{2}$$

where l is the mean length of the magnetic path (meters) and $I_{L\,ave}$ is the current measured by a rectified average ammeter in the output circuit.

Moreover the parameter $\mathcal{F}_{dc}$, is defined as

$$\mathcal{F}_{dc} = \mathcal{F}_1 + \mathcal{F}_b + \mathcal{F}_f \tag{3}$$

where

$$\mathcal{F}_1 = \frac{1}{U}\frac{N_1 I_{1\,ave}}{l}, \quad \mathcal{F}_b = \frac{1}{U}\frac{N_b I_{b\,ave}}{l},$$

$$\mathcal{F}_f = \frac{1}{U}\frac{N_f I_{f\,ave}}{l} \tag{4}$$

$I_{1\,ave}$, $I_{b\,ave}$, and $I_{f\,ave}$ are direct components (time average values) of the currents that flow in signal, bias and feedback windings, and N_1, N_b, and N_f are correspondingly their number of turns (per core). The convention is used that N_b is a positive or negative number according to whether the bias magnetomotive force $N_b I_b$ is such to aid or to oppose the magnetomotive force $N_1 I_{1\,ave}$, of the signal. A similar sign convention is used for N_f which will be a positive quantity in the case of positive feedback, but shall be negative for negative feedback action.

Figure 2. General dimensionless output characteristics of magnetic amplifiers

Figure 4. Dimensionless transfer characteristics for magnetic amplifiers with feedback, negligible commutation and feedback ratio $(N_f/N_s) = 1$ for various values of $\mathcal{B}_m$

Thus for the external feedback amplifier of Figure 1(C), $N_f = \pm N_t$, while for the self feedback of Figure 1(D), in which feedback and output windings coincide, $N_f = \pm N_2$.

The full lines of Figure 2 have been calculated from equations 17 and 18 of Appendix I. The abscissa $\mathcal{F}_L$ has been chosen as in equation 2 on the basis of rectified average value of output currents as the curves convey in this form more directly usable information on the performance of feedback amplifiers, as shown later. If so desired, similar dimensionless curves in terms of rms or of peak output currents can be plotted from equations 15 or 16. More simply these curves also may be obtained from the average value currents of Figure 2 by means of the no-load form factor and peak factor curves shown in Figure 12. (It may be of interest to note that such form and peak factors do not depend on the average value of core flux density if an hyperbolic sine function is used to represent the experimental normal magnetization curve.)

The dotted curves of Figure 2 represent in general dimensionless form the same relationship between $\mathcal{B}_m$ and $\mathcal{F}_L$ for different values of the parameter $\mathcal{B}_0 = \mu B_0$ where B_0 is the direct component of core flux density. These curves are calculated using equation 18 of Appendix I and are plotted in Figure 2 as they are useful for the study of commutation phenomena as discussed in Appendix I. (They also can be useful in the analysis of transients, in which the growth or decay of the direct component of the average core flux is essential, as indicated for example in reference 5.) The representation of Figure 2 evidences also that $\mathcal{B}_0$ depends not only on $\mathcal{F}_{de}$ but on $\mathcal{B}_m$ as well.

By crossplotting the full line curves of Figure 2, Figure 3 is obtained in which $\mathcal{F}_L$ is plotted as function of $\mathcal{F}_{de}$ for various values of $\mathcal{B}_m$. The curves show the limitations of the so-called "turns ratio law."[3] This law states an approximate equality of ampere turns per core of rectified average output currents and of average ampere turns per core of signal, bias, and feedback current; that is, in our notation $(1/2)\,\mathcal{F}_L = \mathcal{F}_{de}$. It is seen actually that for high enough values of $\mathcal{F}_{de}$, these curves are nearly straight lines, whose slopes however vary for different values of $\mathcal{B}_m$, (as expressed also by equation 19 in Appendix I). In other terms the turns ratio law, obtained on the assumption of so-called square magnetization curves, may not apply too well to materials with gradually varying incremental permeability with which this analysis is concerned.

Amplifiers Without Feedback

The full line curves of Figure 2 allow the immediate evaluation of the operating point of any amplifier without feedback, (Figures 1(A) and 1(B), for which $N_f = 0$), for any specific instance for which data of design (resistance, number of turns of the various windings, core cross section and mean length) and magnetization curve of the material (expressed in terms of the parameters U and u) and for which signal and bias currents and alternating voltage across the output windings are given.

"Load lines" expressing the possible points of operation of a magnetic amplifier for various values of signal current and fixed a-c supply voltage and load also can be plotted in dimensionless form on the chart of Figure 2. For instance the known elliptical load lines that result for a resistive load R_L under the approximate assumption of sinusoidal output current can be represented on the chart also with ellipses whose axes coincide with the coordinate axes. The intercept $\mathcal{B}_{mi}$ of such ellipses with the ordinate axis is the value of $\mathcal{B}_m$ corresponding to zero output current (infinite "reactance" of the output windings). Thus if the supply voltage is V_{rms} it follows from equation 1.

Figure 5. The feedback correction factor γ as a function of $\mathcal{F}_L$ for various values of $\mathcal{B}_m$ and k for $(N_f/N_s) = +1.0$ in full line and $(N_f/N_s) = -1.0$ in dotted line

Figure 6(A) (left). Dimensionless transfer characteristics for magnetic amplifiers with feedback showing the influence of commutation for $\mathfrak{B}_m = 1.0$, $(N_f/N_3) = +1.0$, and various values of k

Figure 6(B) (right). Dimensionless transfer characteristics for magnetic amplifiers with feedback showing the influence of commutation for $\mathfrak{B}_m = 3.0$, $(N_f/N_3) = +1.0$, and various values of k

$$\mathfrak{B}_{mt} = u\frac{\sqrt{2}V_{rms}}{N}\frac{1}{\omega A} \tag{5}$$

On the other hand the intercept with the abscissae axis is

$$\mathfrak{F}_{Lt} = \mathfrak{B}_{mt}/\mathfrak{R} \tag{6}$$

where

$$\mathfrak{R} = uU\frac{\pi}{2}\frac{l}{N^2\omega A}R \tag{7}$$

If R_3 is the resistance of winding N_3, then $R = R_L + 2R_3$ for the amplifier shown in Figure 1(A) and $R = R_L + 1/2\ R_3$ for the amplifier shown in Figure 1(B). More general elliptical loci that result for non-rectified loads consisting of resistance and inductance or the straight lines into which loci degenerate for the case of purely inductive loads and negligible power winding resistance R_3 can be plotted on the chart of Figure 2 for any specific instance of given a-c supply voltages and load impedances in a similar way.

The Amplifier with Feedback

The dimensionless curves of Figure 2 apply for amplifiers with feedback also, and similar load lines can be drawn. In these cases however the variable $\mathfrak{F}_{de}$, as defined in equation 3, includes the term $\mathfrak{F}_f$ which depends directly on the average value $I_{f\,avg}$ of current flowing in the feedback windings.

Transfer curves, expressing $\mathfrak{F}_L$ as function of the dimensionless control magnetomotive force $\mathfrak{F}_C = \mathfrak{F}_1 + \mathfrak{F}_b$ for given values of $\mathfrak{B}_m$ are obtained immediately from the curves of Figure 3, whenever the assumption can be made that

$$I_{f\,avg} = I_{L\,avg} \quad \text{for the external feedback amplifier} \tag{8}$$

and

$$I_{f\,avg} = \frac{1}{2}I_{L\,avg} \quad \text{for the self-feedback amplifier.}$$

The dimensionless magnetomotive force $\mathfrak{F}_C$ of the control windings (bias and signal) is then related to $\mathfrak{F}_{de}$ by

$$\mathfrak{F}_C = \mathfrak{F}_1 + \mathfrak{F}_b = \mathfrak{F}_{de} - \frac{N_f}{N_1}\frac{1}{2}\mathfrak{F}_L \tag{9}$$

where for the external feedback case $N_f = \pm N_4$ and for the self feedback case $N_f = \pm N_3$. The curves of Figure 4 have been obtained under the assumption given in equation 8 for a "feedback ratio" $N_f/N_3 = 1$.

As shown later quantitatively, condi-

tions may arise however for which I_{fave} is greater than the value given in equation 8. This phenomenon has been recognized already in the early papers of T. Buchhold,[4] and has been mentioned also in a discussion of references 3 and 7 by D. B. Corbyn. In the wording of Corbyn, the feedback circuit is highly inductive and hence a decaying current may be expected to continue flowing through some of the feedback rectifiers when the other feedback rectifiers have already initiated conduction. (This phenomenon is not to be confused with the reverse conduction that may be due to imperfect rectifiers.) This simultaneous conduction of all feedback rectifiers (called "commutation") is explained in the analysis[1] considering that the assumption of a sinusoidally alternating core flux superposed on a direct component of flux implies the need of even harmonics of magnetomotive forces. In the simple amplifier (Figure 1A) these magnetomotive forces are supplied by even harmonic currents flowing in the signal windings, while for the amplifier (Figure 1B), harmonic currents are induced in the signal windings as well as in the external loop of the output windings in the inverse ratio of the resistances and in the direct ratio of the number of turns. Likewise for the amplifiers (Figures 1C and 1D) a contribution to the total need of even harmonics of magnetomotive force should be expected to be provided by current flowing in the feedback windings, this contribution being dictated by ratios of resistances and numbers of turns and being not necessarily coincident with the even harmonics which result simply from the rectification of the currents supplied by the a-c source.

The detailed analysis established in reference 1 does not need to be repeated here. In Appendix I however it has been found convenient to elaborate upon the results of the previous analysis, and a correction factor γ has been calculated for the feedback ratio so as to take into account the rather involved commutation phenomena in a directly usable form. With the introduction of this factor, equation 9 is modified into the more general form

$$\mathcal{F}_C=\mathcal{F}_1+\mathcal{F}_b=\mathcal{F}_{dc}-\gamma\frac{N_f}{N_L}\frac{1}{2}\mathcal{F}_L \tag{10}$$

which no longer requires the not always acceptable assumption $I_{fave}=I_{Lave}$ or $(1/2)$ I_{Lave} as indicated in equation 8.

The factor γ depends on the number of turns of the signal, bias, and feedback windings and the resistance of their cir-

Figures 9(A) and (B). Average feedback current as a function of the rectified average load current in the amplifier with feedback showing the effect of resistance of the control circuits on the feedback ratio, for positive and negative feedback action $(N_f/N_L)=\pm 1.0$

The dotted points are for $k=0.02$ and the crosses for $k=0.20$. Figure 9(A) is for $\mathcal{B}_m=1.0$ and Figure 9(B) is for $\mathcal{B}_m=3.0$

cuits. Moreover, it is a function of the direct and alternating components of core flux densities. As shown in equations 18 and 25 of Appendix I, γ can be conveniently expressed in terms of the variables $\mathcal{B}_m$, $\mathfrak{F}_L$, and k. Here

$$k=\left(\frac{N_1}{N_f}\right)^2\left(\frac{R_f}{R_C}\right) \tag{11}$$

R_f is the resistance of the feedback circuits during commutation; $R_f=2R_4+R_r$ for the external feedback amplifier and $R_f=2R_4+2R_r$ for the self feedback amplifier where R_r is the forward resistance of one rectifier arm. R_C is the resistance of the combined signal and bias circuits as given by

$$\frac{1}{R_C}=\frac{1}{2R_1}+\left(\frac{N_b}{N_1}\right)^2\left(\frac{1}{2R_b}\right) \tag{12}$$

where $2R_1$ and $2R_b$ are the resistances of the signal and bias circuits respectively. Thus in the case of no bias windings

$$k=\left(\frac{N_1}{N_4}\right)^2\left(\frac{2R_4+R_r}{2R_1}\right)$$

for the external feedback amplifier, and

$$k=\left(\frac{N_1}{N_3}\right)^2\left(\frac{R_3+R_r}{R_1}\right)$$

for the self feedback amplifier circuit.

Figure 5 shows values of γ as a function of $\mathfrak{F}_L$ as calculated from equation 25 for fixed values of k and $\mathcal{B}_m$, assuming $N_f/N_2=+1.0$ (as is the case for self feedback or for external feedback with 100 per cent feedback ratio). Similar curves also can be plotted for other values of the feedback ratio N_f/N_2 using equation 25. It is seen that γ is very close to unity when k is large, that is, when signal or bias windings offer comparatively easy paths to induced currents satisfying the needs of even harmonics of total magnetomotive force. (In the reply of Gale and Atkinson to Corbyn's discussion of reference 7, this fact is expressed by saying that the inductance of the feedback circuit is shunted by the rather low reflected resistance of the coupled control circuits.) It is in such cases that the simplifying assumption given in equation 8 can be accepted, that is commutation phenomena are ignored. On the other hand, small values of k (as they may occur in feedback amplifiers in which forcing resistors are used to improve the speed of response), cause a considerable increase of feedback action.

Figures 6(A) and 6(B) indicate transfer characteristics obtained for $\mathcal{B}_m=1.0$ and $\mathcal{B}_m=3.0$ and $N_f/N_2=+1.0$, for various values of k. These are found directly from Figures 3 and 5 in the following manner. Knowing the value of $\mathcal{B}_m$ the appropriate transfer curve of $\mathfrak{F}_L$ versus $\mathfrak{F}_{d.c.}$ can be found from Figure 3. Then from the value of k given by equation 11, γ can be found using Figure 5 for the various values of $\mathfrak{F}_L$. $\mathfrak{F}_C$ is then found from equation 10. It is seen again that small values of k may give transfer characteristics which are considerably steeper than the ones obtained for the same values of $\mathcal{B}_m$ in Figure 4 in which commutation was neglected. On the other hand no appreciable differences are found when k is large ($k\geq 1.0$).

Commutation phenomena are of particular significance, for instance, when the resistance of the signal circuit is increased by means of forcing resistors, as frequently used to improve the speed of response. For the case of positive feedback, the forcing resistor shifts upon the feedback windings the burden of providing the $\mathfrak{F}_{d.c.}$ needed for a given output $\mathfrak{F}_L$. That is, as $\mathfrak{F}_f$ increases, the need for $\mathfrak{F}_1$ decreases (as shown clearly by the increased slope of the transfer characteristics of Figure 6).

(C)

Figure 9(C). Calculated dimensionless transfer characteristics for $\mathcal{B}_m=3.0$, $(N_f/N_1)=1.0$ for $k=0.20$ and $k=0.02$ showing the influence of commutation with experimental points

Figure 11. The angle of commutation σ as a function of $-(H_2/H_1) \times (N_2/N_f)$ for various values of k as calculated using equation 24

Figure 13. Hyperbolic sine co-ordinate paper for the determination of the constants u and U in the analytical approximation of the normal magnetization curve $H = U \sinh uB$

In fact somewhat particular conditions may even be thought of, for which the use of a forcing resistor results in an increase of power gain. A phenomenon of this kind is obtained for instance for the following conditions

$\mathfrak{G}_m = 1.0$, $\mathfrak{F}_L = 40$, thus $\mathfrak{F}_{id} = 35.9$ (from Figure 3)

With $(N_4/N_3) = 1.0$, $k = 1.0$ and no forcing resistance, $\mathfrak{F}_f = 20.5$ and $\mathfrak{F}_C = 15.4$. Assuming a bias $\mathfrak{F}_b = 12.5$, then $\mathfrak{F}_1 = 2.9$.

If now a forcing resistor is used to increase the resistance of the signal circuit five times, for very large resistance of the bias circuit (as needed if fast speed of response is wanted) $k = 0.20$ and $\mathfrak{F}_C$ decreases to 13.8 as shown in Figure 6. In this case $\mathfrak{F}_f$ is increased to $\mathfrak{F}_f = 22.1$ and for unchanged bias $\mathfrak{F}_b = 12.5$, $\mathfrak{F}_1$ reduces to $\mathfrak{F}_1 = 1.3$. Hence the power loss in the signal circuit is decreased in spite of the increase of circuit resistance.

On the other hand, commutation phenomena may be reduced considerably, if so desired (for example, in order to lessen the burden of the feedback rectifiers) by connecting a capacitor of large enough value directly across the signal or bias windings, thus providing an easy path for the even harmonics of currents through such windings.[6] The resistance of the signal or bias circuit to be used in the expression for k is then only the resistance of the windings.

Samples of Experimental Checks

Samples of experimental results are given as obtained on amplifiers with the following core specifications: material, Hypernik; core area $A = 4.2\ 10^{-4}$ square meter; mean length $l = 0.181$ meter.

The normal magnetization curve, obtained with a moving coil fluxmeter, is shown in Figure 7. In the dimensionless analysis, the magnetic properties of the core are expressed by the two constants U and u of the approximation $H = U \sinh uB$. These constants are obtained as $U = 127$ ampere turns per meter $u = 4.6$ square meter per weber, and the resulting analytical approximation is compared with the experimental curve in Figure 7. (Convenient methods for the determination of these constants are indicated in Appendix II.)

Figure 12. No load form factor and peak factor curves as a function of $\mathfrak{G}_m$

The basic circuits of Figures 1(A) and 1(B) have been used with $N_1 = 2{,}000$ turns, $R_1 = 100$ ohms, $N_2 = 2{,}000$ turns, $R_2 = 120$ and $N_b = 0$. The rms volts per turn (at 60 cycles) have been varied from 0 to 0.12 and the rectified average output current has been measured for fixed values of average signal current I_1 varying from 0 to 200 milliamperes. A few typical experimental values are converted into dimensionless values as per equations 1 to 4 and plotted then on the dimensionless chart.

An additional sample of experiments on operation with load also is represented in Figure 8. For this the amplifier (Figure 1A), with the same winding data as before, has been used with a series load resistance $R_L = 5{,}040$ ohms and with a fixed 60-cycle supply voltage of 338 volts rms. The output currents corresponding to various values of signal, after reduction to

dimensionless values, have been marked as crosses in Figure 8 in which also the corresponding theoretical elliptical locus ($\mathfrak{B}=0.033$, intercepts $\mathfrak{B}_{m1}=3.40$, $\mathfrak{F}_{L1}=102$) is shown.

Figure 9 evidences the increase of average value of feedback current resulting from commutation phenomena. For this the external feedback amplifier of Figure 1(C) has been used with the same hypernik cores and following winding specification: $N_1=2{,}000$ turns, $R_1=120$ ohms, $N_b=20$, $N_f=2{,}000$ turns, $R_f=216$ ohms (including rectifier resistance as given after equation 11). The number of turns in the signal windings has been kept fixed at 500 turns, but using two different values of R_1 equal to 33.7 and 337 ohms so as to give two different values of k equal to 0.20 and 0.02 respectively (as per equation 11). Constant 60-cycle voltages of 98 rms and 294 rms volts (such as to give $\mathfrak{B}_m=1.0$ and $\mathfrak{B}_m=3.0$) were applied at the amplifier output terminals and simultaneous readings of output current and current in the feedback windings were taken by varying the signal. Figures 9(A) and 9(B) show the comparison of the experiment with theoretical values of the analysis for the two values of k and for positive and negative feedback action. The 45-degree line plotted corresponds to the simplified case of no commutation ($k=\infty$). Figure 9(C) presents experimental checks on the over-all influence of this commutation phenomena upon the transfer curves.

Appendix I

Tables II and III of reference 1 give expressions for the instantaneous values of currents in the windings of the feedback amplifiers (Figures 1A and 1C). These expressions result from the simultaneous solution of magnetomotive-force equations for each of the three periods shown in Figure 2 of reference 1.

The time average values of the currents are related by

$$N_{d_0}I_{d_0\,\mathrm{avg}}=N_1I_{1\,\mathrm{avg}}+N_bI_{b\,\mathrm{avg}}+N_fI_{f\,\mathrm{avg}}=lH_0 \quad (13)$$

$$NI_{L\,\mathrm{avg}}=\frac{4}{\pi}l\left[H_1+\frac{1}{3}H_3+\frac{1}{5}H_5+\ldots\right] \quad (14)$$

where $N_{d_0}I_{d_0\,\mathrm{avg}}$ is the total direct component of magnetomotive force of each core and $NI_{L\,\mathrm{avg}}$ is the rectified average output magnetomotive force as defined initially. Similarly the rms value is

$$NI_{L\,\mathrm{rms}}=\frac{2}{\sqrt{2}}l\sqrt{H_1^2+H_3^2+H_5^2+\ldots} \quad (15)$$

while the peak value is

$$NI_{L\,\mathrm{peak}}=2l[H_1+H_3+H_5+\ldots] \quad (16)$$

The coefficients H_0, H_1, H_3 and so forth are obtained from Table I, reference 1, with $v=0$, if the simplified approximation $H=U\sinh uB$ is adopted for the normal magnetization curve. Thus

$$N_{d_0}I_{d_0}=lU\mathfrak{g}_0(uB_m)\sinh(uB_b) \quad (17)$$

$$NI_{L\,\mathrm{avg}}=\frac{4}{\pi}lU2\left[\mathfrak{g}_1(uB_m)-\frac{1}{3}\mathfrak{g}_3(uB_m)+\ldots\right]\cosh(uB_b) \quad (18)$$

where B_m is the crest of the alternating component of flux density and B_b the direct component.

The significant dimensionless quantities used earlier in this paper are immediately recognizable from equations 17 and 18, namely NI/lU, uB_m, and uB_b. From these equations the curves of Figure 2 (or Figure 3) are plotted. The slopes of the general transfer curves of Figure 3 are given by

$$\frac{\mathfrak{F}_L}{\mathfrak{F}_{d_0}}=\frac{8}{\pi}\frac{m}{n}\frac{1}{\tanh uB_b} \quad (19)$$

where

$$m=2\left[\mathfrak{g}_1(uB_m)-\frac{1}{3}\mathfrak{g}_3(uB_m)+\ldots\right] \quad (20)$$

$$n=\mathfrak{g}_0(uB_m) \quad (21)$$

For large values of $\mathfrak{F}_L$ and $\mathfrak{F}_{d_0}$ this ratio $\mathfrak{F}_L$ to $\mathfrak{F}_{d_0}$ approaches constant values as seen in Figure 3.

In order to relate $N_{d_0}I_{d_0}$ to the signal and bias ampere turns, N_fI_f must be determined. In fact the simultaneous conduction of all feedback rectifiers that occurs during commutation periods results in an increase of the instantaneous values of the current in the feedback winding, above the values of instantaneous rectified output during such periods. Thus the average feedback current $I_{f\,\mathrm{avg}}$ is greater than $I_{L\,\mathrm{avg}}$ in the external feedback amplifier and is greater than (1/2) $I_{L\,\mathrm{avg}}$ in the self feedback amplifier. The time average feedback current, including the effect of commutation, results from equations 19 or 24 of reference 1 for the amplifiers of Figures 1D and 1C respectively and is given in both cases by

$$N_fI_{f\,\mathrm{avg}}=\frac{2lU}{\pi(1+k)-2\sigma}\left\{\frac{N_f}{N_2}(1+k)2\times\left[\mathfrak{g}_1(uB_m)\cos\sigma-\frac{1}{3}\mathfrak{g}_3(uB_m)\cos 3\sigma+\ldots\right]\times\cosh(uB_b)+2\left[-\frac{1}{2}\mathfrak{g}_2(uB_m)\sin 2\sigma+\frac{1}{4}\mathfrak{g}_4(uB_m)\sin 4\sigma-\ldots\right]\times\sinh(uB_b)\right\} \quad (22)$$

where σ is the "angle of commutation" of Figure 2, reference 1, and k is given by equation 11 of this paper. If $\sigma=0$(that is, if the commutation is negligible)

$$N_fI_f=\frac{N_f}{N_2}\frac{1}{2}NI_L \quad (23)$$

which corresponds to the dimensionless equation 8. However for $\sigma\neq 0$ it is seen that $N_fI_f>(N_f/N_2)(1/2)(NI_L)$.

An additional expression results for N_fI_f by matching the values of feedback currents (Table II or III, reference 1) at the instants of transition between different periods. Hence a transcendental equation is obtained for σ in terms of k, (N_f/N_2) and (H_2/H_1). Upon neglecting even harmonic terms greater than the second this equation is written as

$$-\frac{H_2}{H_1}\frac{N_2}{N_f}=(1+k)\times\frac{2\cos\sigma-[\pi(1+k)-2\sigma]\sin\sigma}{\sin 2\sigma+[\pi(1+k)-2\sigma]\cos 2\sigma} \quad (24)$$

In order to find σ the ratio $-(H_2/H_1)$ has been plotted now in Figure 9 in terms of $\mathfrak{B}_m$ and $\mathfrak{B}_0$ (which, for any output, are obtained directly from the dotted curves of Figure 2). Figure 10 gives then σ as a function of $-(H_2/H_1)(N_2/N_f)$ for various values of k.

An evaluation of the amount by which the feedback current is increased by commutation is expressed in terms of the feedback correction factor of equation 10. From equations 18 and 22

$$\gamma=\frac{N_2}{N_f}\frac{N_fI_f}{NI_L}=\frac{\pi}{2}(1+k)\frac{p}{m}-\frac{\pi}{2}\frac{q}{m}\frac{N_2}{N_f}\tanh uB_b \quad (25)$$

where

$$p=\frac{4}{\pi(1+k)-2\sigma}\left[\mathfrak{g}_1(uB_m)\cos\sigma-\frac{1}{3}\mathfrak{g}_3(uB_m)\cos 3\sigma+\ldots\right]$$

$$q=\frac{4}{\pi(1+k)-2\sigma}\left[\frac{1}{2}\mathfrak{g}_2(uB_m)\sin 2\sigma-\frac{1}{4}\mathfrak{g}_4(uB_m)\sin 4\sigma-\ldots\right] \quad (26)$$

For any given $\mathfrak{B}_m$, γ can be evaluated for various k as function of $\mathfrak{B}_0$ or, using the dotted curves of Figure 2, also as function of $\mathfrak{F}_L$ as plotted in Figure 5.

Appendix II. The Constants U and u of the Core Material

The magnetic properties of the core material appear in the dimensionless quantities of this analysis in the form of the two constants U and u of the approximation $H=U\sinh uB$ chosen to fit the normal magnetization curve. Two points of this experimental curve are sufficient to determine such constants. Their choice has to be made with some judgment as the resulting fitting function truly will coincide with the experimental data at the origin and at these two points only. Two points, one (H',B') in the region of higher magnetizing intensity and the other (H'',B'') somewhere slightly "below the knee" are likely to provide a stisfactory fit.

The determination of the unknown values of U and u appearing in the two simultaneous equations $H'=u\sinh uB'$ and $H''=U\sinh uB''$ is facilitated by the use of the chart of Figure 13, in which $y=\sinh uB=\sinh uB'(B/B')$ is plotted as a function of uB' for given constant values of the ratio (B/B'). The abscissa of a vertical line intercepting the two curves $(B/B')=(B''/B')$ and $(B/B')=1$ at two values y'' and y' such that

$(y'/y'') = (H'/H'')$, gives the wanted uB' and thus u.

Moreover U is found as $U = (H'/y') = (H''/y'')$. As an example the determination of U and u for the experimental curve of Figure 7 is obtained on the basis of the two points ($H' = 2{,}440\ AT/m$, $B' = 1.290\ w/m^2$) and ($H'' = 266\ AT/m$, $B'' = 0.775\ w/m^2$) for which $(y'/y'') = 9.8$. In Figure 13 the abscissa of the vertical line in this case is $uB' = 5.9$ and thus $u = 4.6$ and also $U = 12.7$.

Additional attempts to fit the experimental curve also can be tried for different initial choices of the points (H',B') and (H'',B''). Actually for magnetic materials such as hypernik and similar silicon steel alloys, for which the simplifying assumptions of the analysis[1] apply best, comparable over-all accuracy seems to result from calculations based on apparently different fits, as long as the fitting function is reasonably close to the experimental normal magnetization curve in the range of higher magnetizing intensities.

Underground Hydroelectric Power Stations in Sweden

ÅKE RUSCK
NONMEMBER AIEE

G. WESTERBERG
NONMEMBER AIEE

SWEDEN has practically no resources of coal, oil, or natural gas. There are comparatively large resources of peat, but it has not yet proved economically possible to utilize it on a large scale. Water power resources, however, are large and it has been estimated that the resources capable of economic development amount to about 50,000 million kilowatt-hours a year, corresponding to a little more than 7,000 kilowatt-hours per head of the population. By the end of 1949, the power stations already in existence were capable of producing approximately 16,000 million kilowatt-hours a year, about 30 per cent of the economically available resources.

A fairly low head is generally utilized in Swedish water power stations. The head is frequently less than 150 feet and only in rare cases exceeds 300 feet. The natural falls are often very extended in length, with the result that a gathering of the head must be brought about. The mean flow of water in the larger rivers amounts to about 10,000 cubic feet per second at the mouth. The water flow to be developed at the plants amounts to an average of 1.5 or 1.6 times the average flow of water. The amount of water to be developed, which is then relatively great, is spread over only a few (2 to 4) units. Kaplan turbines have hitherto been used for heads up to 110 feet, and for greater heads, Francis turbines are used. The biggest units now under installation will have a capacity of about 100,000 kw.

The General Layout of a Power Station

When planning and constructing a power station, all efforts are made to utilize the head of the falls and rapids of the river in the best possible way, and to obtain the lowest possible annual costs. In the economic calculation, the interest on the capital outlay, the cost of normal operation, maintenance costs, and depreciation are taken into account.

In order to find the most economical position for the dam, a preliminary survey is made in which are calculated the cost of constructing the dam, and the headrace and tailrace for different alternatives. In order to make the final choice between the various alternatives, the annual costs for all parts of the plant are compared, as they will vary according to the dam-site. Account is then taken of the value of the head and the storage reservoir, the price that will have to be paid for the land to be flooded, the cost of the coffer dams and diversion of the river during construction, the cost of log flumes, the machine station, mechanical and electric equipment and power transmission to the switchyard, the surge basin, and so forth. When a rock-fill dam has been constructed, the most economical results were sometimes achieved when it was so situated that the rock blasted out for other purposes sufficed as filling for the dam.

When comparing underground and surface power stations, it must be remembered that maintenance costs for tunnels and rock rooms are lower than for the corresponding parts of a surface station where concrete has to be employed to a great extent. This also is true of depreciation, as rock has a far longer life than concrete. In Sweden, we reckon on an annual maintenance expenditure and depreciation of 1 per cent of the cost of construction for rock work, while the corresponding figure for concrete work is 1.7 per cent.

The progress of the last few decades in the technique of digging and blasting have made it economically possible to concentrate the head of falls and long rapids in a single power station. Swedish rivers are, however, not usually of such a nature as to permit high dams to be built. The river banks are seldom more than a few meters higher than the natural water level and are surrounded by farm land and built-up areas which are too valuable to submerge on a large scale. These obstacles do not occur in the mountainous districts, but owing to the great width of the valley floors, high dams are not usually constructed there. Normally, therefore, the concentration of the greater part of the head must be done by means of river-bed clearances, tunnels, and canals.

The water intake is often placed at the dam itself, but on occasions it has been found more convenient to conduct the water via a headrace canal to an intake situated so as to give a shorter length of the conduits from the intake to the turbines or downstream from the power station, thereby reducing the conduit costs and, when the penstocks are shortened, also simplifying the regulation of the turbines. Penstocks are employed except for very low heads. If the ground is composed of good rock and its surface is on a sufficiently high elevation, the machine station is constructed underground, and the tailrace either partially or wholly as a rock tunnel. The penstocks are in that case, for the main part, placed vertically. If the ground is earthy, it is necessary to conduct the water through sloped penstocks and place the power station further from the intake, so that it will be situated at the ground surface, with no discharge tunnel being required. It is not usually necessary to construct large power stations in this way in Sweden.

Paper 50-149, recommended by the AIEE Power Generation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 16, 1950; made available for printing April 13, 1950.

Figure 1 (left). Machine hall with uncovered rock walls

Figure 2 (above). Machine hall with uncovered rock walls

If, in rocky ground, a surface station was to be built instead of an underground station, it would be necessary either to maintain the turbines in deep shafts as in the underground station and place the generator hall only at the ground surface, or to construct the station somewhat like that described for a station in earthy ground, using sloping penstocks and a tailrace canal. A station with deep turbine pits and long driving shafts is usually more expensive to construct than an underground station in rock and is, in addition, less advantageous from the operational point of view. A station with long penstocks makes regulation of the turbines more difficult (relief valves are often required) and the additional cost for the extended length of the penstocks on account of a sloped location is usually considerably greater than the saving which results from having a shorter or no discharge tunnel. The cost of the power station itself also must be taken into account when making a comparison. This will not be more expensive when located down in the rock than at the surface, as the expense of blasting out the larger masses of rock is partially compensated for by the diminished cost for walls and roofing. When planning an underground station, however, allowance must be made for the cost of transport arrangements to the ground surface and, when there are long tunnels, also for surge basins.

There is no general rule as to whether a station should be built as an underground station or not. For the sake of clarity, however, it should be mentioned here that in every case where an underground station has been built in Sweden, it has been because it was the most economic solution for the power plant as a whole. The improved safety attained thereby in time of war was only a welcome extra advantage and not the primary reason.

The cost for power plants with underground power stations recently built, or at present under construction, is calculated at about $80 per kilowatt maximum output for stations with a capacity of 100,000-300,000 kw based on the 1949 year's price level and at an exchange rate of $1 = 5.18 Swedish kronor.

The Design of the Underground Hydroelectric Power Stations

Intakes and Penstocks

For underground stations, the intakes are constructed on much the same principle as for surface stations.

As mentioned previously, the penstock shafts are usually placed vertically for underground stations. They are equipped with steel tubes, either detached from the rock surface, or embedded in concrete. The lower horizontal part of the tube, which needs to be rigidly anchored, is always embedded in concrete. In certain cases where the rock was particularly good, steel tubes have been dispensed with altogether to a depth of approximately 250 feet below the upstream water level and the rock surface of the shaft lined with reinforced concrete instead.

Machine Stations

When constructing an underground station, the removal of blasted rock from the machine station and the discharge tunnel has often been done by trucks through special transport tunnels. When these tunnels also could be used as an entry for rotors, turbines, and so forth, a considerable saving was effected as lifts were not then necessary for this purpose. In those cases, the heavy machinery was transported to the machine hall directly from the nearest railway station on special trailers drawn by tractors.

As in a surface station, heating is generally supplied by the surplus heat from the transformers, but the need for heat in underground stations is less than in surface station. The supply of fresh air, on the other hand, requires more complicated arrangements. The fresh air is introduced usually either through a special shaft or through a shaft which also performs another function. Ar-

Figure 3. Rock roof covered with reinforced gunite

Figure 4. Tunneling unit cost, based on the 1949 year's price level

The costs comprise drilling, blasting, ventilation, mucking, transport (by trucks) and dumping, drainage, electric energy and administration, but not interest of outlay during the construction period, or costs of such transport arrangements as, for instance, transport tunnels

rangements are sometimes made for the air to be lead over a cold water surface, for instance, the surge basin, in order to reduce its moisture. The generators generally have a closed water-cooling circuit and the transformers also are water cooled insofar as their surplus heat is not employed for heating purposes. Large quantities of fresh air are therefore not required.

The problem of drainage has not caused any great difficulty in underground stations. To prevent leakage in the machine hall, in some cases a drainage tunnel has been constructed a little upstream, of and parallel to, the machine hall. A network of holes is then drilled from the drainage tunnel in which water seeping from the rock is accumulated and subsequently lead out to the discharge tunnel.

It has often been possible to leave the rock of the machine hall walls uncovered in underground stations, Figures 1 and 2. Protective or reinforcement work has always been employed for the roofs. In one recently completed machine hall with a width of 60 feet, the roof was strengthened with long anchor rib steel bars, grouted in drilled holes, and the rock surface covered with gunite, reinforced with two layers of welded steel netting, Figure 3. The netting was fastened by rock dowels and by welding to the anchor bars. The gunite and anchor bars replaced a concrete arch, but were considerably cheaper.

Figure 5. Underground station with comparatively low head

Discharge Tunnels and Surge Basins

Lifts are seldom used for removing blasted rock from the rock rooms and tunnels. It is removed by diesel-engine trucks directly from the blasting place to the dump site. When driving a long tunnel, special transport tunnels are blasted out which are usually given a slope of about 1 to 8 (in one case 1 to 7). The transport tunnel is usually made wide enough to permit trucks to meet at any point, so that as many trucks can be brought to the cutting face as the excavator is able to load. It is therefore the capacity of the excavator which determines the time of loading, and consequently it is of great importance to obtain the most suitable excavators.

Tunnels with a cross-sectional area of up to about 1,200 square feet are blasted out by the full face method. When the tunnel section is larger than this and the rock is very good, the lower portion of the tunnel sometimes is first blasted out by this method and the excavation is subsequently extended up to full height. If the rock is not quite so good, the upper section is blasted out first and the lower section afterwards, as this avoids the necessity of cleaning the roof twice. When the upper section is the last to be blasted out, the bulk from this portion can be removed continuously, but this advantage is lost when the lower section is the last to be blasted. Usually the bottom of the tunnels are given a slight slope towards the drainage pumps to minimize the trouble from seepage during construction.

The cost of excavating a tunnel of say, 1,000 square feet cross-sectional area is usually about $2.90 per cubic yard. Figure 4 illustrates the variation in the cost per unit of volume to tunnel area when the cost of possibly needed reinforcement is excluded. The cost of reinforcement generally has not exceeded 5 per cent of the cost of excavation, but in one case the cost has been as high as 25 per cent.

When the downstream water level varies greatly, the whole of the discharge tunnel is usually placed below the lowest water level so as to prevent a large ineffective cross-sectional area to come up at low water levels. When the downstream water level varies within narrow limits and the tunnels are short, they have in some cases been placed sufficiently high to obtain a free water level and to avoid the necessity of a surge basin. In other cases, the surge basin has been placed downstream of the machine station either by increasing the height of the tunnel a sufficient length immediately downstream of the draft tubes, or by blasting out a special basin with connection to the discharge tunnel near the outlet of the draft tubes. The connection between the surge basin and the discharge tunnel has sometimes been choked. The cost of constructing the surge basin on the downstream side of an underground station is partially compensated for by the fact that because the penstocks become short the devices for diminishing rises in pressure and surge on the upstream side are simplified.

The Transformer Rooms and Switchyards

Immunity to aerial bombardment is highly valued at the more important power stations. When the machine hall is located below the ground, thereby giving the units a high degree of protection, the transformers are usually also placed in rock rooms so that all the vital parts of the installation are equally well protected from air attack.

In power stations with a voltage stepped up to 200 kv or more, it is usually more expensive to place the transformers in rock rooms than on the surface, although in the latter case it is customary to surround them with splinterproof protection. The choice of placing the transformers in rock-rooms is attributed sometimes to the fact that at low generator voltage it may be cheaper to draw up

Figure 6. Underground station with comparatively long tailrace tunnel

high-tension cables rather than low-tension cables to the ground surface. High-tension switchyards, on the other hand, are never located in the rock as the great space required makes the cost of blasting prohibitive.

The simplification of the operation usually is the determining factor in placing the control room. It is, therefore, as a rule placed near the machine hall.

Description of Some Power Plants

A description of some of the underground stations is shown in the following, in order to illustrate whenever it has been considered advisable to place them underground. The plants are shown in Figures 5 to 8. The profile of the rivers have been made on a horizontal scale 40 times less than the vertical scale. The detail of the power station on the drawings is on the same scale as the vertical scale of the river profile, but the cross-section of the dam is on one half of this scale. In all cases, the surface of the tail water level has been taken as zero.

Plant 1

Plant 1, Figure 5 is in operation. The site for the dam was determined by the fact that the river bed narrows here and that the ground was of rock. The spillway occupies nearly the whole length of the dam. The intake is placed in the dam and the water is conducted to the turbines by penstocks that are mainly vertical. The rock downstream of the dam is so low that only part of the machine station has a rock covering. An arch-shaped reinforced concrete roof has been constructed near the ground surface over the machine hall and the control department. It would have been possible to have made the whole station underground by moving the machine station further inland, but the cost of the whole plant would thereby have been increased. The tailrace is a rock tunnel 0.6-mile long, and a canal in earthy soil is 0.8-mile long. Access to the machine station is via a sloping tunnel. The transformers are located in rock rooms beside the machine hall and from here, 200-kv oil-pressure cables run up to the switchyard on the ground surface.

Plant 2

Plant 2, Figure 6, is in operation. The machine hall is placed in the rock near the dam. The ground slopes steeply downstream from the dam, and the cost of the dam would have increased considerably more than the cost of the tunnel would have decreased if the dam had been placed further downstream. A 3-mile long tunnel forms the tailrace. Removal of the blasted rock during construction was carried out partly through a lift shaft at the power station, partly by a transport tunnel from the middle of the tailrace tunnel, and partly by way of a sloping road at the downstream end of the tailrace tunnel. Access to the machine hall is by a lift shaft. The control room and transformers are placed on the ground surface.

Plant 3

Plant 3, Figure 7, is under construction. The dam is of the rock-fill type with an impervious core. The tailrace consists of a tunnel 1.8-miles long with a cross-sectional area of 2,040 square feet. The most advantageous site for the dam proved to be where the excavated rock from the tunnel and power station most nearly sufficed for the supporting parts of the dam. Mainly vertical penstocks lead from an intake situated in the dam down to the machine station in the rock. In the river bed a short distance upstream from the dam a marked fault zone runs through the rock and this has resulted in the dam and the power station being placed somewhat further downstream than would otherwise have been desirable. A railway track runs right up to the plant. Access to the machine hall is via a lift shaft with an unloading hall on the ground surface. The transformers and control room are situated underground beside the machine hall, and the transformers are connected to the switchyard by 380-kv oil-pressure cables.

Plant 4

Plant 4, Figure 8, is under construction. It will be possible to shorten the conduits by transferring water from one arm of the river to another. The head-race tunnel will be 2.3 miles long with a free water surface and the tailrace tunnel will be 1.7 miles long and placed below the lowest downstream water level. The reason why the head-race tunnel is given a free water surface is that the tunnel is

Figure 7. Underground station with comparatively high rockfill dam

Figure 8. Underground station with both headrace and tailrace tunnel

intended to be used also for logging operations. The rock is good for the main part, but reinforcement proved necessary for parts of the roof and walls of the machine hall. Access to the machine hall, which is nearly 300 feet below the ground surface, is for heavy machinery by means of the transport tunnel used for removing blasted rock during the construction period. For transport of lighter equipment and persons there will be installed elevators. The transformer and control rooms are being constructed as for Plant 3.

Operational Experiences

As the center of power production has been moved to the northern part of the country, a great many operational problems have arisen. The power plants in the northern part of Sweden are generally developed to a less degree in relation to the average water flow than those in the southern part, and the plants are continuously operated at full capacity for long periods. It is therefore necessary that they have great operational reliability and that only short standstill times are needed.

The attendance of an underground station does not differ essentially from that of a surface station. It cannot be pointed out any direct disadvantage in the operation or maintenance of an underground station in comparison with a surface station.

In a large power station two machinists are normally on duty at each shift, regardless if the station is located above or below the ground surface. One man remains continuously in the control room, while the other is employed inspecting the turbines, generators, auxiliary machinery, dam, and so forth. In those cases when the control room is on the ground surface and the machine hall below the ground, the latter is not always continuously manned. If the station has a small number of units it is then considered sufficient to have occasional inspections by one of the machinists. If the number of units is great it is normally the practice to keep one man permanently in the machine hall even when it is located on the ground surface.

No staff difficulties have been noticed. A machinist in an underground station naturally has no opportunity of seeing the sun during his shift, but apart from this, there should be no difference between working in an underground station and in a surface station. An advantage of the underground station worth mentioning is that the climatic conditions are more constant. It is conceivable that psychological factors may have some influence, but no such difficulties have hitherto arisen with the staff.

It should be mentioned in this connection that there is a vast difference between the conditions under which a power station machinist works and, for example, a miner. The former worksin a dry, well heated, ventilated and illuminated place which is hardly to be distinguished from a normal room while the latter suffers discomfort from dampness, darkness, cold and rough rock faces. As a further proof that work in underground stations does not imply any discomfort, may be cited the fact that there is no noticeable tendency among the staff to apply for a discharge or transfer to a surface station. The staff of the underground station, have the same working hours, holidays, and social advantages as any other power station staff.

Evaluation of Lightning-Arrester Lead Length and Separation in Co-ordinated Protection of Apparatus Against Lightning

L. E. SALINE
ASSOCIATE AIEE

CO-ORDINATED protection of station equipment against lightning damage has proved to be a vital factor in system operating economics. Now, however, with increasing acceptance of the reduced insulation concept in voltage classes of 115 kv and above, the co-ordinated protective approach merits more exact quantitative appraisal of the over-all protective scheme.

It generally is known that the voltages at the insulation to be protected may be above the protective level held at the lightning arrester.[1,2,3,4] These overvoltages can be attributed primarily to the following causes:

1. The lightning-arrester lead length; that is, the length of lead joining the top of the lightning arrester to the overhead line plus the length of lead joining the bottom of the lightning arrester to the lead or mat between the lightning arrester and the protected apparatus.

2. The lightning-arrester separation; that is, the horizontal distance from the lightning arrester to the protected apparatus.

3. The degree of grounding of both the lightning arrester and the protected apparatus.

Hence, for maximum protection the lightning arrester should be connected directly across the insulation to be protected. In actual practice, however, this is not always done, and an evaluation of the probability of whether or not the insulation will be protected by the lightning arrester in these cases has been largely a qualitative one, based to some extent on past operating experience.

The purpose of this paper is to extend the knowledge on lightning-arrester performance and application for lightning arrester installations on transmission systems of 115 kv and higher, giving particular consideration to the effects of circuit configuration and lightning-arrester discharge currents. Field and laboratory investigations have been made of the effect of circuit configuration, but these have been limited in scope. This investigation has utilized the differential and transient analyzers in making possible, conveniently and economically, a generalized evaluation of a large number of different combinations of circuit geometry, lightning-arrester discharge currents and system voltage levels. As a result, it is hoped that the application of arresters can be placed on a more quantitative basis.

Summary and Conclusions

In addition to lightning arrester separation, lead length, and ground resistance, the evaluation of the degree of protection necessary for a given station depends on the anticipated lightning discharges through the lightning arrester and these, in turn, are a function of isokeraunic level, system shielding and grounding, and other surge-limiting devices or factors. Generally, the results of the study indicate that it is desirable to place the lightning arrester directly across the insulation to be protected to avoid undue risk of overvoltages due to separation, lead length, and ground resistance. This is more important with reduced insulation levels.

Most of the results are derived from lumped constant concept and analysis and were based on the results from experimental investigations; see the section on Analytical Investigation. And in general, also, these results of protected insulation overvoltages caused particularly by the lightning-arrester lead length and separation are considered conservative in so far as they are based largely on an elementary circuit configuration and do not include a bus having several connected circuits.

Based on a lightning-arrester discharge current of 5,000-ampere crest, 1.6×16.5 microseconds (5,000 amperes per microsecond effective rate-of-rise), the specific results from the study are as follows:

For the elementary circuit (that is, one which includes only the lightning arrester connected by conductors to the incoming overhead line and to the capacitor simulating the protected apparatus) there are these conclusions:

1. With typical lightning-arrester connections, the voltage appearing at the capacitor will tend to be a damped oscillatory voltage that increases in maximum value as the lead length in the T-connection, separation, ground resistance, and steepness of front of the impulse current wave increase and the initial capacitor charge and impulse capacitance decrease. For severe discharge currents and the circuit configurations studied the capacitor voltage in per unit of sparkover voltage of the lightning arrester (herein assumed a constant equal to 40 kv per 12-kv station-type lightning-arrester unit) varies between 1.2 and 1.85 for 288-kv systems and between 1.4 and 2.4 for 115-kv systems. These values do not include the effect of initial charge or the attenuation that may be inherent in protected apparatus, Figure 8.

Figure 1. Final equivalent circuit representing lightning-arrester protecting apparatus simulated by impulse capacitance = C. Lightning discharge current is $Y_0(t)$. M is the mutual coupling between loops 1 and 2

R_1, R_2 = equivalent ground resistance
L_3 = equivalent ground inductance
R_A, L_A = equivalent lightning-arrester resistance and inductance
R_4, L_4 = equivalent resistance and inductance of lightning-arrester lead
R_5, L_5 = equivalent resistance and inductance of overhead conductor between lightning arrester and protected apparatus
R_6, L_6 = equivalent resistance and inductance of apparatus lead
C = equivalent impulse capacitance of protected apparatus

See Appendix I and the section on Analytical Investigation for methods used in arriving at the foregoing equivalent parameters

2. The time-to-crest of the capacitor voltage increases as the impulse capacitance of the protected apparatus, lead length, and separation increase. The time-to-crest of the capacitor voltage is practically independent of ground resistance and wave shape for the values assumed in the study and varies between 0.16 and 1.25 microseconds, Figure 9.

3. As the system voltage level increases, the per-unit capacitor voltage decreases, as shown in Figure 8.

4. Of primary importance in controlling the overvoltage at the capacitor is the lightning-arrester capacitor separation, Figure 4. The separation range from 0 to 10 feet is particularly critical:

a. The effective loop inductance associated with each foot of lead length in the T-connection increases critically from zero to approximately 0.28 microhenry per foot in the range of separations from 0 to 10 feet and then increases slowly for larger separations from 0.28 microhenry per foot at 10 feet to 0.304 microhenry per foot at 50 feet, Figure 3.

b. With the V-connection (zero lead length) the capacitor voltage does not exceed double the maximum voltage drop across the lightning arrester for separations greater than 10 feet.

5. The length of the lightning-arrester lead is important since the lead is effectively a voltage source that contributes to the capacitor voltage in proportion to its length, Figure 5.

6. In the connection of the lightning arrester to the overhead line and the protected apparatus through appreciable lengths of conductor, the V-connection should be used rather than the T-connection. This becomes of increasing importance in applications to apparatus designed with reduced insulation.

7. Studies of a variety of transformers indicate that the representation of a transformer by an impulse capacitance gives the correct natural oscillations, but the magnitudes of the oscillations obtained with a transformer are of the order of 25 per cent less than those obtained with the equivalent capacitor due to inherent transformer attenuation.

8. The effect of the oscillatory voltage on the apparatus insulation is important in determining the breakdown of the insulation; that is, for transformer insulation, a test wave composed of a 1.5×40-microsecond full wave of 1.0 per-unit crest plus a superimposed oscillation (4 to 5 cycles) of 0.3 per unit is equivalent to a chopped wave with a crest of 1.15 per unit.

In a complex circuit typical of a large modern station having several lines and transformer banks connected to a common bus, Figure 12, the lines and transformers connected in parallel at the bus will reduce the severity of the effect of the surge entering the station, Figure 14. However, a lightning arrester is desirable at each transformer in addition to those on the line side of the line circuit breakers to protect against:

1. Line strokes if all the lines and transformers are not connected to the station.

2. Failure of direct-stroke shielding between the main bus and transformers.

3. Switching surges.

Experimental Basis for Analysis

To establish some basic facts pertaining to the discharge of current surges through lightning arresters, some laboratory experiments were performed involving a surge-current generator and a rectangular loop. In one vertical leg of the loop there was inserted a capacitor and in additional tests a transformer; in the other vertical leg there was inserted a lightning arrester. The current discharge used in these tests had a wave shape of 1.6×16.5 microseconds with an effective rate-of-rise exceeding 5,000 amperes per microsecond. These tests indicated the following:

1. The voltage appearing across the capacitor consisted of a damped oscillatory wave superimposed upon a unidirectional impulse similar to that expected in a circuit consisting of lumped constants of inductance, capacitance, and resistance. Similar results have been reported from other laboratory and field experiments.[2,4,9]

Figure 4 (left). Capacitor voltage and time-to-first-crest as a function of separation *D*. Lightning current discharge = 5,150 amperes, 1.6× 16.5 microseconds

Figure 6 (right). Mutual inductance of equal leads in V-connection of lightning arrester

2. The laboratory results could be checked and predicted analytically from lumped circuit concepts and from known and calculated circuit constants based on the geometry of the loop.

3. A transformer can be represented by a lumped capacitance as far as natural oscillations are concerned, but the first crest of the oscillatory component of the voltage at the transformer is approximately 25 per cent less than that obtained with an equivalent capacitor substituted for the transformer. Transformer impulse capacitances were measured from the order of several hundred to several thousand micromicrofarads.

4. The initial charge on the capacitor due to any charging voltage from the surge preceding the sparkover of the lightning arrester tends to decrease the magnitude of the oscillatory component of the voltage at the capacitor resulting from the current discharge through the lightning arrester and its leads after sparkover. It is to be expected that some initial charge is obtained in the majority of cases in service.

5. The magnitude of the oscillatory component of voltage at the capacitor may be appreciably decreased if a V-connection instead of a T-connection at the lightning-arrester line terminal is used, particularly if the length of the vertical lead in the T-connection is such that the inductive drop in the lead is appreciable relative to the drop across the lightning arrester.

Analytical Investigation

Equivalent Circuit

Since the results of experimental investigations demonstrate that the problem of lightning-arrester protection as affected by circuit configuration can be solved for some practical cases using the lumped constant theory, the equivalent circuit employed in further studies by analyses is shown in Figure 1 and is the result of considerations in the succeeding paragraphs and in Appendix I.

The lightning-arrester lead length, as already defined, is represented by the lumped inductance L_4, which is calculated in conjunction with L_4 as outlined in Appendix I. To include some damping due to the nonlinear thyrite lightning arrester, its resistance R_A is assumed constant at 4 ohms per lightning-arrester unit. The nonlinearity of the thyrite was considered in the voltage drop in the resistance of the lightning arrester by measuring the voltage $E_{ab}(t)$ for a lightning-arrester discharge current $Y_0(t)$. Typical current and voltage curves are shown in Figure 2 and were employed in the analysis as explained subsequently. The resistances R_1 and R_3, together with the inductance L_3, represent a metallic ground connection between the lightning arrester and the transformer or protected apparatus. The equivalent leakage resistances R_1 and R_3 to ground were assumed to be equal and given a value of 5 ohms. It should be recognized, however, that R_1 and R_3 are actually variable quantities that will depend on the nature of the impinging wave. The inductance L_4 of the ground was chosen as the lumped inductance of a solid conductor connecting the transformer and lightning-arrester ground leads, and it was calculated as explained in Appendix I. Also a mutual inductance, M, coupling the loop involving the overhead line with the loop involving the ground lead joining the protected apparatus to the lightning arrester is calculated as explained in Appendix I. The resistances of the lightning-arrester lead, transformer lead, and transmission line were calculated for an average frequency of 700,000 cycles per second as outlined in Appendix I. The values of impulse capacitance C were chosen as 200 micromicrofarads, 1,000 micromicrofarads, and 3,000 micromicrofarads, which are representative for bushings,[7] circuit breakers, and a wide range of transformer ratings.

Figure 5 (left). Capacitor voltage and time-to-first-crest as a function of lightning-arrester lead length *l*. Lightning current discharge = 5,150 amperes, 1.6× 16.5 microseconds

Figure 7 (right). Capacitor voltage and time-to-first-crest as a function of impulse capacitance, C. Lightning current discharge = 5,150 amperes, 1.6× 16.5 microseconds

Analysis of Equivalent Circuit

The analysis for the equivalent circuit of Figure 1 is presented in detail in Appendix II. As indicated there, a general solution involves cumbersome expressions, and, hence, the formula for capacitor voltage is not given in final form. The determination of the capacitor voltage $E_{DR}(t)$, however, was accomplished by arranging the network equations for solution on the differential analyzer[4] and studying the effects of network configuration, system voltage levels, and various wave shapes of lightning-arrester discharge currents. Also the equivalent circuit was set up in miniature on the transient analyzer[5,6] to check the differential analyzer study and to extend the study to other conditions and more complex circuits.

It is to be noted in Figure 1 that the effect of the lightning current $Y_0(t)$ discharging through the lightning arrester and its leads to ground is represented, for the purpose of analysis, by an equivalent voltage generator in each loop, where the generated voltage in one loop consists of the sum of the lightning-arrester voltage $E_{ab}(t)$ and the lead-length drop $E_{01}(t)$ while in the other loop the voltage consists of the ground-resistance voltage drop $E_{02}(t)$.

Results

The results of the analyzer studies are illustrated and discussed in this section. The voltages on the capacitor simulating the protected apparatus are expressed in per unit of the spark-over voltage of the lightning arrester, and this is assumed to be a constant of 40 kv per 12-kv lightning-arrester unit regardless of the nature of the lightning discharge. The lightning-arrester ratings associated with the various voltage levels are for effectively grounded systems, as shown in Table I.

Lightning-Arrester Separation

Lightning-arrester separation, defined previously, appears to be one of the most important factors in determining the overvoltages above those held at the lightning arrester. Since the inductance of a loop increases with the area enclosed by the loop, the inductance that may be assigned to the lightning-arrester lead length as a part of the circuit being studied will increase with the arrester separation, as shown in Figure 3. Thus, a specified lightning current discharging through a given lightning-arrester lead length induces a voltage in the loop involving the lightning arrester and capacitor which increases critically for lightning-arrester separations in the range from 0 to 10 feet and increases slowly for separations greater than 10 feet. Figure 4 illustrates this for two voltage levels, showing also the effect of an initial charge $E_{DR}(o)$ on the capacitor at the time of sparkover of the lightning arrester. From Figure 8 it should be noted that even for a V-connection overvoltages exist, hence, for finite separations, regardless of lead length, overvoltages can be expected to occur. It is interesting to note that the time-to-crest increases nearly linearly with separation.

Table I

System Voltage Level, Kv	Lightning-Arrester Rating, Kv	Proposed Number of 12-Kv Lightning-Arrester Units*	Spark-over Voltage at 40 Kv Per 12-Kv Lightning-Arrester Units, Kv*

230	180	15	600
288	228	19	760

* "Lightning-arrester units" refers to 12-kv station type.

Lightning-Arrester Lead Length

The lightning-arrester lead is effectively a voltage source that contributes to the capacitor voltage in proportion to its lead length, as shown in Figure 5. Actually the importance of this additional voltage source per foot of lightning-arrester lead depends on the separation and the length of the lead, as shown in Figure 3. There it is shown that for a given separation the inductance per foot increases nearly 20 per cent as the lead length increases from 10 to 30 feet. The induced voltage acting on the circuit due to the lightning-arrester lead also depends on the steepness of the front of the lightning current discharged through the lightning arrester. Figure 5 shows that the time-to-crest also increases as the lead length increases.

The equivalent of zero lead length may be attained through the use of a V-connection. As shown in Figure 6, the mutual inductance of the leads in the V-connection is a function of the geometry of the V. Thus, as R/l is increased, the V-connection becomes increasingly effective as the mutual inductance decreases.

Ground Resistance

The voltage drop in the ground resistance is effectively another voltage source which tends to increase the capacitor voltage. However, as long as there is a good connection between the lightning arrester and protected apparatus grounds, the ground leakage resistance, R_1 and R_2 of Figure 1, is not critical. It can be shown analytically that the time-to-crest is practically independent of the ground resistance.

Impulse Capacitance

For the circuit configurations and discharge currents studied here, the capacitor voltage decreases slowly as the impulse capacitance increases, as shown in Figure 7. However, for certain combinations of lightning-arrester transformer separations, lightning-arrester voltage characteristics, and impulse capacitances the capacitor voltage can vary as the impulse capacitance as previously reported in a discussion of reference 5.

Figures 7 and 9 indicate that the time-to-crest of the capacitor voltage increases with capacitances and actually the time-to-crest increases according to the square root of the impulse capacitance.

It is to be emphasized that the results given herein for a capacitor representation of a transformer are pessimistic to the

extent that the oscillatory component of the voltage be decreased by the order of 25 per cent at the first crest due to transformer attenuation.

Initial Capacitor Charge

If there is an initial charge on the capacitor due to the impinging wave, it has been shown analytically and demonstrated experimentally that the capacitor voltage after lightning-arrester spark-over is less than when there is no initial capacitor charge, as shown in Figures 4 and 5. Since the initial voltage at the capacitor is a function of the wave shape of the surge voltage prior to lightning-arrester spark-over and since specific information is not available on the correlation between the wave shape of the lightning arrester current and the pre-sparkover voltage, the results presented here are for zero initial voltage and are consequently conservative.

Composite Characteristics

The complete relation between circuit geometry, system voltage level, and capacitor voltage is illustrated graphically in Figure 8 for a lightning current discharge through the lightning arrester having a wave shape of 5,000-ampere crest, 1.6×16 microseconds and an effective rate-of-rise of 5,720 amperes per microsecond. The graphical data include separations from 10 to 50 feet, lead lengths from 0 to 30 feet, impulse capacitors from 200 to 3,000 micromicrofarads, and system voltage levels 115 kv to 288 kv. The dashed line on Figure 8 illustrates the use of the curves for $D=15$ feet, $l=20$ feet, and $C=1{,}000$ micromicrofarads.

Figure 9 gives the complete relationship for time to first crest for the same circuit geometry, and is independent of system voltage level.

Figure 10 shows the components of capacitor voltage due to the lightning arrester, lead length, ground resistance, and initial charge for a high-voltage system using 16 lightning-arrester units. These data are based on a discharge current of 10,000 amperes, 1.6×16.5 microseconds showing somewhat more severe voltages than would be obtained with a similar wave of 5,000-ampere crest.

Wave Shape of Lightning Current Discharge

The choice of a representative wave shape of lightning current discharged by the lightning arrester on which to base protection studies is somewhat arbitrary, depending on the probability of occurrence and the degree of protection economically feasible and desirable. Involved in these considerations are the isokeraunic level, system shielding, system grounding and other protection or surge-reducing factors. Based on field data gathered at stations[2,10,11,12] the lightning-arrester discharge currents include the values shown in Table II.

Figure 11 illustrates the decrease in the capacitor voltage as the effective rate-of-rise of the lightning current wave discharged through lightning arrester becomes smaller.

For the capacitor voltages, the time-to-first-crest and the time-to-maximum-value are the same for current impulses having steep fronts but may be different for current impulses with relatively slowly rising fronts. In the case for $C=200$ micromicrofarads the maximum value may occur on the second or third voltage crest for slow-front waves. Since the maximum crest value differs only slightly from the value at first crest for most cases, the time-to-crest is generally given as the time-to-first-crest. The physical implication of the first crest of the capacitor voltage appearing in time before the crest of the lightning-arrester voltage is that the capacitor voltage will be sustained for a larger number of cycles than if the first crest voltage across the capacitor appears in time after the crest of the lightning-arrester voltage.

System Voltage Level

As the system voltage level increases, the per-unit capacitor voltage decreases as shown in Figure 8. This is so because, percentage-wise, the induced voltage resulting from the lightning-arrester lead length and the voltage drop in the ground resistance becomes proportionately smaller relative to the increase in maximum voltage drop across the lightning arrester as the system voltage and the number of lightning-arrester units increase. Another interpretation of the results is that the geometry of the lightning-arrester-protected apparatus network is less critical the higher the system level for any given discharge current.

The time-to-crest of the oscillatory overvoltage is essentially independent of voltage level and is given in Figure 9 for various circuit configurations.

System Configuration

The elementary circuit which was considered in all of the foregoing represents the simplest setup or station. It is the purpose in this section to discuss the surge phenomena in a more complex station arrangement. The station circuit arrangement chosen is shown in Figure 12 and was set up in miniature on the transient analyzer[8,9] as shown in Figure 13.

The 16-unit station-type lightning arrester at point 1 in Figure 12 is assumed to discharge a 5,150-ampere, 1.6×16.5-microsecond current wave and the voltage at point 1, E_1, is composed of the voltage drop across the lightning arrester and the induced voltage resulting from the vertical lead in the T-connection. It is desired to determine the voltage at the various circuit breakers and transformers for different numbers of lines and transformers connected to the main 230-kv bus. In the study all the lightning ar-

Crest, Amperes	Wave Shapes, Microseconds	Effective Rate-of-Rise, Amperes per Microsecond (10 Per Cent–90 Per Cent)	$\left[\frac{di}{dt}\right]_{t=0}$, Amperes per Microsecond	Maximum Voltage Drop Across One 12-kv Lightning Arrester Unit, Kv
5,150	1.6×16.5	5,720	14,600	44.7
5,000	4.5×16	1,730	2,500	43
4,600	10×20	550	1,000	39.2

resters except the one located at point 1, Figure 12, were disconnected during the discharge of the lightning arrester at point 1. This was done in order that the voltages measured at the other lightning-arrester locations would indicate the actual voltages against which the disconnected lightning arresters must protect.

The impedance Z in Figure 13 is a surge impedance representing additional lines and transformers, since it was found that the addition of lines and transformers to the main bus was effectively the same as the addition of a surge impedance of 400 ohms for each of the lines or transformers connected to the bus.

The results of the study are summarized in Figure 14. Some typical oscillograms for one line and one transformer connected to the main bus are shown in Figure 15. These do not include the effect of attenuation due to transformer damping or the initial charges on the apparatus at the time of sparkover of the lightning arrester.

Although it is indicated that the effect of surges entering a station from a transmission line is decreased as the number of pieces of apparatus and the number of lines connected to the main bus are increased, it should be mentioned that lightning arresters also are necessary at the transformers, as well as at the line circuit breakers, to protect against:

1. Line strokes if all the lines and transformers are not connected to the station.
2. Failure of direct-stroke shielding between the main bus and transformer.
3. Switching surges.

Relation of Overvoltage to Volt-Time Characteristic of the Apparatus

The exact interpretation of the effect of the oscillatory overvoltage on the protected insulation necessitates voltage characteristics of the insulation obtained with damped oscillatory waves. It has been shown[13] that a test wave composed of a 1.5×40-microsecond full wave of 1.0 per-unit crest plus a superimposed oscillation (4 to 5 cycles) of 0.3 per unit is equivalent to a chopped wave with a crest of 1.15 per unit. Since the American Standards Association chopped-wave test is 1.15 per unit of the American Standards Association full-wave test, it is concluded[13] that a damped high-frequency oscillation of 0.3 per unit can be superimposed on the full-wave of 1.0 crest without stressing the transformer major insulation greater than the American Standards Association chopped-wave test (1.15 per-unit crest).

It is of interest, therefore, to consider the maximum separation (for V-connection in the elementary circuit) which would limit the oscillatory voltage to 0.3 per unit of the lightning-arrester voltage for a discharge current of 5,150 amperes, 1.6×16.5 microseconds. Figure 16 presents the oscillatory component of capacitor voltage (calculated by subtracting lightning-arrester voltage from the results of Figure 8) corrected for 25-per cent transformer damping for the V-connection and C = 1,000 micromicrofarads. This corrected capacitor voltage and the lightning-arrester voltage are plotted as a function of the number of lightning-arrester units. It is interesting to note that the oscillatory component increases until approximately 15 lightning-arrester units are employed and then decreases as more lightning-arrester units are used in the circuit. The decrease beyond 15 lightning-arrester units can be attributed to the damping resistance which increases approximately linearly with the number of lightning-arrester units. The oscillatory component would be zero if the number of lightning-arrester units were increased to the point of critical damping for the circuit configurations considered.

From the data in Figure 16 it is possible to derive a table of separations for the elementary circuit which results in a 30-per cent overshoot; see Table III.

For oscillations limited to 30 per cent of the lightning-arrester voltage (due to a discharge current of 5,150 amperes, 1.6×16.5 microseconds) the separations for the V-connection and with assumed transformer damping of 25 per cent are plotted on Figure 16. These separations do not consider any reductions of capacitor voltage which might arise from the initial charge on the capacitor or from complex station configurations. It is

Appendix I. Considerations of Parameters for Equivalent Network

Resistance Calculations

For solid conductors the resistance[14] at very high frequencies (R_∞) may be expressed as

$$R_\infty = \frac{R_S}{2\pi r_0} \text{ ohms per meter}$$

where

$$R_S = \frac{1}{\sigma\delta} = \text{surface resistivity}$$

σ = conductivity in mhos per meter
δ = depth of current penetration in meters
r_0 = conductor radius in meters

Consider copper conductor at a frequency of 700,000 cycles per second. (Range in study 0.4 to 3.0 megacycles per second.)

$$\delta = \frac{0.0660}{\sqrt{f}} = \frac{0.0660}{\sqrt{700{,}000}} = 0.0000788 \text{ meter}$$

$$\sigma = 5.8\times10^7 \text{ mhos per meter}$$

$$R_S = \frac{1}{\delta\sigma} = \frac{1}{(5.8\times10^7)(0.0000788)} = 2.19\times10^{-4}$$

For

$$r_0 = 1/4 \text{ inch} = 0.0063 \text{ meter}$$

$$R_\infty = \frac{R_S}{2\pi r_0} = \frac{2.19\times10^{-4}}{2\pi(0.0063)} = 5.55\times10^{-5}$$

ohms per meter $= 1.69\times10^{-5}$ ohms per foot

Inductance Calculations

Consider the general circuit of Figure 17. The electromagnetic image[15] of a current is that current, or system of currents, which, when placed at proper positions behind a surface, produce the same magnetic effect in front of the surface, in the region containing the original current, as actually is produced by the induced magnetization upon the surface. When the bounding surface is a plane, the electromagnetic images coincide in position with the optical images of the original current which would be produced if the surfaces were mirrors with their silvered surfaces presented toward the region which contains the current. In the case under consideration the bounding plane is the zero current plane which is assumed to be parallel to the conductors 1 and 2. Hence, the images of conductors 1 and 2 are shown in their proper positions where

$$D_{ac} = D_{bd} \quad \text{and} \quad D_{ab} = D_{cd}$$

and the i_1 and i_2 are loop currents as indicated. Thus the zero current plane has been removed effectively from the picture and the inductances can be calculated without regard for the zero current plane.

Reference 16 gives formulae for calculating the total inductance or the equivalent inductance of each conductor side of the rectangular loop which is l centimeters long and d centimeters wide and has conductor of radius ρ centimeters. Such rectangles might be loops 1 and 2 of the circuit under consideration. It is shown here that the inductance of a rectangle of length a and breadth b is

$$L = 2(L_a + L_b - M_a - M_b) \qquad (1)$$

where L_a and L_b are the self-inductance of the two sides of length a and b taken alone, M_a and M_b are the mutual inductances of the two opposite pairs of length a and b respectively.

The self-inductance of one side may be determined from

$$L = 0.002\left[l \log_e \frac{l+\sqrt{l^2+\rho^2}}{\rho} - \sqrt{l^2+\rho^2} + \frac{l}{4} + \rho\right] \text{ microhenrys} \qquad (2)$$

where

Figure 14. Transformer and circuit-breaker voltage as a function of lines and transformers on main 230-kv bus in per unit of crest E_1 = 740 kv

E_1 = Lightning-arrester voltage plus induced voltage due to current discharge of 5,000 amperes, 1.6×16.5 microseconds through 15 feet of lead length in the assumed T-connection

Subscripts on voltages correspond to measuring points on Figures 12 and 13

ρ = radius
l = length of wire in centimeters

The mutual inductance of two parallel filaments is given as

$$M = 0.002\left[l \log_e \frac{l+\sqrt{l^2+d^2}}{d} - \sqrt{l^2+d^2} + d\right] \text{ microhenrys} \qquad (3)$$

where ρ = radius
l = length
d = separation of the wires in centimeters

The total inductance L calculated in equation 1 could be proportioned to the sides a and b, according to the values of L_a, L_b, M_a, and M_b. The principle illustrated in equation 1 also is employed in the calculation of L_4 and L_5 of Figure 1.

Figure 12. One-line schematic diagram of a high-voltage switching station. Circled numbers represent measuring points

Figure 13. Equivalent miniature circuit of Figure 12 for study on transient analyzer

Actual pi-section constants: L = 320 microhenrys and C = 900 micromicrofarads
Lightning-arrester resistance = 10 + R_A = 600, C_1 = 500 micromicrofarads and C_2 = 1,000 micromicrofarads
Circled numbers correspond to measuring points on Figure 12

The mutual effect between loops 1 and 2 is

$$M_{12} = M_{ab} - M_{ac} + M_{cd} - M_{bd} = 2M_{ab} - 2M_{ac} \tag{4}$$

where the mutual inductances are calculated by equation 3. For the mutual effects of conductors a and b when dealing with voltages between a and b and the current plane

$$M = \frac{M_{12}}{2} = M_{ab} - M_{ac} \tag{5}$$

If conductors 1 and 2 are relatively long with respect to their height above the zero current plane, then equations 1, 2, and 3 can be simplified. Hence, if $l \gg d \gg \rho$, then for l in centimeters

$$L = 0.002\, l \left[\log_e \frac{2l}{\rho} - \frac{3}{4} \right] \text{ microhenrys} \tag{2A}$$

and

$$M = 0.002\, l \left[\log_e \frac{2l}{d} - 1 \right] \text{ microhenrys} \tag{3A}$$

However, if the permeability of the conductor is μ and that of medium outside is unity

$$L = 0.002\, l \left[\log_e \frac{2l}{\rho} - 1 + \frac{\mu}{4} \right] \text{ microhenrys} \tag{2B}$$

and for high frequency ($\mu = 0$)

$$L = 0.002\, l \left[\log_e \frac{2l}{\rho} - 1 \right] \text{ microhenrys} \tag{2C}$$

If in equation 1 $L_b = M_b = 0$, if equations 2A and 3A are substituted for L_a and M_a, and if L is divided by $2l$, then the standard equation for the inductance of a long line $d/2$ centimeters above the zero current plane is approximately given by

$$L_{ll} = 0.004 \log_e \frac{d}{\rho} \frac{\text{microhenrys}}{\text{centimeter}} \tag{1A}$$

Similarly the mutual inductance for two conductors a and b with positions above the zero current plane as defined in the figure can be approximated from equations 3A and 5 to find that

$$M = 0.004 \log_e \frac{D_{ac}}{D_{ab}} \frac{\text{microhenrys}}{\text{centimeter}} \tag{5A}$$

Appendix II. Analytical Solution of Figure 1

From Figure 1 the following loop equations in matrix form from which the voltage across the capacitor C is to be determined may be written as

$Y_1(p)$	$Y_2(p)$
$(R_1+R_2+R_A+R_4+R_5+R_6)+p(L_A+L_4+L_5+L_6)+\frac{1}{pC}$	$pM+R$
$pM+R$	$R_1+R_2+pL_3$

$$= \frac{E_{G1}(p) - \dfrac{E_{DE}(0)}{p} + E_{G2}(p)}{E_{G2}(p)}$$

Figure 15. Typical oscillograms of voltages measured with one line and one transformer on main bus. Time scale in microseconds. Numbers on oscillograms refer to measuring points on Figures 12 and 13

If

$r = R_1 + R_2 + R_A + R_4 + R_5 + R_6$
$L = L_A + L_4 + L_5 + L_6$
$R = R_1 + R_2$

and solving for $Y_1(p)$, there results

$$Y_1(p) = \frac{\left[E_{G1}(p) - \dfrac{E_{DE}(0)}{p}\right][R + pL_3] + E_{G2}(p)[p(L_3 - M)]}{\Delta(p)}$$

Solving for the voltage across the capacitor

$$E_{DE}(p) = \frac{1}{pC} Y_1(p) + \frac{E_{DE}(0)}{p}$$

$$= \frac{\left[E_{G1}(p) - \dfrac{E_{DE}(0)}{p}\right][R + pL_3] + E_{G2}(p)[p(L_3 - M)]}{C\, LL_3 \left[\left(1 - \dfrac{M^2}{LL_3}\right)p^3 + \left(\dfrac{R}{L_3} + \dfrac{r}{L} - \dfrac{2MR}{LL_3}\right)p^2 + \left(\dfrac{rR}{LL_3} + \dfrac{1}{LC} - \dfrac{R^2}{LL_3}\right)p + \dfrac{R}{LL_3C}\right]} + \frac{E_{DE}(0)}{p}$$

where

$E_{G1}(p) = [E_{ab}(p) + Y_0(p)(pL_4 + R_4)]$
$E_{G2}(p) = R_1 Y_0(p)$
$E_{DE}(0)$ = initial voltage on capacitor
M = mutual inductance between loops 1 and 2.

The inductances L_3, L_4, L_5, and L_6 are determined from the equations in Appendix I, considering loops 1 and 2 as separate rectangular circuit loops with their images below the zero current plane. Similarly the mutual inductance M between loops 1 and 2 may be calculated from the equations in Appendix I.

The voltage across the capacitor as a function of time is obtained by taking the inverse Laplace transform as

$$E_{DE}(t) = \mathcal{L}^{-1} E_{DE}(p) = \mathcal{L}^{-1}\left(\frac{Y_1(p)}{pC} + \frac{E_{DE}(0)}{p}\right)$$

Figure 16. Oscillatory component of capacitor voltage as a function of separation and lightning-arrester units for V-connection and corrected for transformer damping = 25 per cent

Separation curve with V-connection to limit oscillatory voltage to 30 per cent of lightning-arrester voltage as a function of lightning-arrester units

Discussion

J. R. Meador (General Electric Company, Pittsfield, Mass.): This timely paper contains a very thorough analysis of the pertinent factors involved in the important problem of lightning-arrester location. While it has been apparent from theoretical considerations that lightning arrester lead length and separation from the transformer should be kept to a minimum for maximum protection, the numerical values have not been available.

It is obvious from this paper that more field data on rates of current rise through lightning arresters in stations are needed. As these data become available for the various conditions of station and line shielding, the authors' method of calculation can be used to arrive at an increasingly-accurate appraisal of proper lightning arrester location.

The authors bring out an interesting point in showing that separation between lightning arrester and transformer has an effect that increases rapidly up to a separation of ten feet, and beyond ten feet increases more slowly. Thus, if the permissible separation is ten feet or more under one set of conditions, a reduction in oscillation voltage will permit a disproportionately large increase in separation. This fact makes the effect of initial capacitor charge assume greater importance since the precharge reduces the magnitude of the oscillation substantially.

In a station-type lightning arrester where the gap sparkover and resistance voltage are of the same order of magnitude, it would appear that a substantial precharge on the capacitor would exist before the surge current discharged through the lightning arrester. Calculations showing permissible separation with different amounts of precharge would be of interest.

The transformer acts as a capacitor only as seen from its terminals and for a relatively small number of microseconds. For longer times the inductance and resistance become more important. However, for the separations and rates of rise of current considered in the paper, the oscillation frequencies are accurate for a few cycles if the transformer is treated as a capacitor.

The assumption of a permissible 30 per cent superimposed oscillation is correct if the period of the oscillation is less than one or two microseconds. If considerably longer separations are considered, the period will increase, and it may be necessary to limit the magnitude of the oscillation to less than 30 per cent.

A. M. Opsahl (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The authors state that it has been shown that transformer insulation of a given basic impulse level (BIL) will withstand a short superimposed oscillation 30 per cent above the full-wave test. The stress on the insulation is no greater than in the chopped-wave test which is a test voltage 15 per cent above the BIL. Table III of the paper gives recommendations on the maximum separation that should be permitted between the lightning arrester and transformer in a substation. This table is developed on the basis of limiting the voltage oscillation at the transformer to 30 per cent above the lightning-arrester discharge voltage. There is no explanation given for the transition from BIL as a base for the permissible overvoltage oscillation to the lightning-arrester discharge voltage as a base for the permissible over-voltage oscillation at the transformer terminals. Presumably a margin has been assumed between the voltage as limited by the lightning arrester and the voltage that the transformer will withstand. Take for example the 115-kv system voltage. The lightning-arrester voltage is given as 360 kv but the BIL of 115-kv class insulation is 550 kv and the BIL of 92-kv class insulation is 450 kv, 53 and 25 per cent above the lightning-arrester voltage respectively. No values of transformer insulation level are given in the table but it looks like the only combination considered is the reduced rating lightning arrester, reduced insulation level in the transformer, and about 25 per cent margin between the transformer insulation strength and the voltage as limited by the lightning arrester. The margin of 53 per cent between insulation level of a full rating transformer and the characteristic of a reduced rating lightning arrester is not reasonable if it requires that all lightning arresters must be within nine feet of the transformer on 115-kv circuits. Full insulation transformers on 115-kv circuits is common practice at the present time.

Table III of the paper is very misleading when so many of the assumptions leading up to its conclusions are omitted.

W. A. McMorris (General Electric Company, Pittsfield, Mass.): Operating experience has shown that current practices of applying lightning arresters for the protection of station apparatus have been highly successful. Some operators have demonstrated that where transformer insulation levels have been properly co-ordinated with the protective levels afforded by lightning arresters, the insulation levels can be reduced one full class below the normal values, resulting in large savings in the cost of transformers.

Because of the increasing trend toward reduced transformer insulation and the large economies that are possible through close co-ordination of insulation at the higher voltage levels, it is desirable to reexamine critically the margins between lightning-arrester protective levels and transformer insulation strengths. These margins are determined in part by lightning-arrester application practices.

In their analysis the authors have assumed relatively severe conditions. They have indicated, however, that lightning voltages at a protected transformer would be reduced by the connection of additional lines or transformers to the bus, or by precharge on the capacitance of the transformer at the instant of lightning-arrester sparkover.

The probability of the assumed condition of zero precharge, on which Figure 16 and Table III of the paper are based, would appear to be rather remote. Where recommended types of construction have been used, the precharge would approach the lightning arrester sparkover value for any practical rates of rise of voltage and separations between lightning arresters and transformers. This would reduce the voltage oscillation at the transformer far below the value for zero precharge. It would permit a substantial increase in lightning-arrester lead lengths and separations between lightning arresters and transformers without exceeding the suggested maximum value of 30 per cent oscillation.

Regardless of what wave shapes may be established as a basis for co-ordination studies, the operator who desires to obtain the widest possible margin of protection, or to retain a normal margin for severe conditions, should use the V-connection. This was demonstrated by tests which were reported by K. B. McEachron and E. J. Wade in 1931,[1] and has been advocated since that time for installations where the lowest protective level is desired. Also, he should use the minimum possible separation between lightning arresters and transformers, and at stations with several transformer banks, he should install a lightning arrester immediately adjacent to each transformer bank as well as on the line side of the circuit breaker on each incoming line.

E. Beck (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The authors' paper on lightning arrester location, and another by R. L. Witzke and T. J. Bliss[1] contribute considerably to the analysis and resolving of the problem. They are not in agreement. This is a good thing as it means that the matter will be studied further and a sound conclusion reached. The authors' paper requires considerable study to uncover the various assumptions and steps and relations assumed between BILs, lightning-arrester voltages, and voltages at the equipment. Considering for the moment only their basic assumption of lightning arrester voltage in Figure 2 and experience in the field, it is my opinion that their conclusions are too conservative for high-voltage equipment shielded in the manner described in a paper on insulation levels.[2]

Considering the author's assumption of a lightning arrester discharge current of 5,000 amperes per microsecond, together with their Figure 2 and the lightning arrester discharge voltage characteristics indicated there, it would seem that to produce the assumed current rise in the lightning arrester, a voltage would have to be impressed at the lightning arrester terminals immediately after lightning arrester sparkover with an initial rate of rise of some 40 kv in 0.125 of a microsecond per 12 kv of lightning arrester. On a 115-kv system with a 97-kv lightning arrester, this would be about 2,560 kv per microsecond. On a 230-kv system with the 180-kv lightning arrester proposed by the authors, it would be about 4,800 kv per microsecond. What do the authors estimate the probability of such rates of rise of surge voltage in a station shielded in the manner considered in the plans for co-ordination?

The authors appear to have neglected what happens before lightning-arrester sparkover. The paper is not clear on this matter, if they have considered it. It is considered in the Witzke and Bliss paper.

Without shielding, we agree that there is no problem, the lightning arresters should be applied as close to the equipment as possible.

In view of the tendency to install lightning arresters near the transformers, a practice with which we concur, especially where reduced insulation levels are used on high-voltage transformer, another aspect of the question is the voltages ahead of the lightning arresters and their effect on switchgear or metering equipment insulation. This may become the more important question. It should receive attention, and offhand looks like a simpler problem.

J. H. Hagenguth (General Electric Company, Pittsfield, Mass.): The paper explains in detail how traveling waves affect voltages in stations with lightning-arrester protection, principally where only one line enters the station. Previously[1] it has been shown in a general way that large differences in voltage to ground and rate of voltage rise can exist in stations with many incoming lines and extended station bus. This point was recently illustrated by the study of a particular station, the results of which are of interest.

Through the courtesy of Mr. I. W. Gross it was possible to obtain a station diagram of the 138-kv Roanoke Station of the Appalachian Power Company. This station has two busses, normally connected together, each 220 feet long. The transformer bank with its lightning arrester is approximately 400 feet from the nearest line. A potential transformer with its lightning arrester has a distance of 240 feet. Between each circuit breaker and its connected circuit, coupling capacitors are connected between two of the phases and ground for carrier-current communication. The electrical circuit equivalent for transients was set up and studied with the transient analyzer.

Based on traveling wave crests of about 800 kv, the maximum voltage permitted by the line insulators, 0.5x40 microseconds waves were applied and the voltages at various points in the station were measured. It is possible to give only a few of the results.

With a traveling wave coming in over only one line, the voltage at the station entrance was about equal to the traveling wave voltage, about 720 kv. The rate of rise of voltage at this point was 1,900 kv per microsecond. At the potential transformer the voltage was 470 kv with a much slower rate of rise of 905 kv per microsecond, while at the power transformer the voltage was 370 kv, with a still slower rate of rise of 310 kv per microsecond. These results are obtained without lightning arresters connected in the circuit. When lightning arresters are connected to the potential and power transformer, the maximum voltage at the station entrance is not changed. The voltages at the transformers are reduced to the lightning-arrester protective level which was about 350 kv in the model.

Some of the lines are double circuit lines on one tower, and the possibility exists that the same phase of both lines is involved in a lightning transient, particularly from back flashover from a tower with high ground resistance.

In this case conditions at the station entrance of both lines are essentially the same as before, but without lightning arresters the potential and power transformer voltages reach 540 kv and 810 kv respectively. With lightning arresters, the voltages are, of course, again held to about 350 kv. The rate of voltage rise is of the order of 900 and 500 kv per microsecond respectively.

If the lightning arresters are connected at the station entrance and not near the transformers, and the same phase of two circuits is impulsed, voltages of 400 kv and 560 kv are obtained at the potential and power transformer respectively, even though the arrester is still holding about 350 kv at its terminals.

Such studies show that in stations with many lines connected to the bus, considerable differences in voltages to ground and rate of voltage rise can exist at various points in the station.

While the most favorable location of the lightning arrester is near the transformer to obtain a minimum protective level at that point, location of the lightning arrester even 400 feet away from the transformer holds the voltage to about the impulse test level of this particular system. However, if one or more of the lines were disconnected at the time of a lightning disturbance, the impulse test level of the transformer would be exceeded.

L. A. Finzi (Carnegie Institute of Technology, Pittsburgh, Pa.): This paper presents a skillful study of transient phenomena in terms of a lumped-parameter analysis and gives interesting conclusions on the basis of rather typical values of the constants of the equivalent circuit.

It may be pointed out however that an accurate evaluation of the various sinks of energy in the equivalent circuit is most essential as it is their damping action that intervenes to limit appreciably the first overvoltage crest at the apparatus terminals and to further dictate the decay of the subsequent crests. Indeed the total energy to be dissipated in the transient is generally very small—a few watt seconds—but the time available for a safe damping is also exceedingly short, as seen from the insulation volt-time curves.

A most important sink of energy is represented by the lightning arrester nonlinear resistors; for these the authors suggest the use of a value of 4 ohms per lightning-arrester unit. Actually this value may vary considerably for various types of discharge; this circumstance seems to confirm the need for a better agreement upon reasonable standard current surges that was raised from various parts in the discussion of a companion paper.[1]

Another important sink can be seen in the drainage by gradual propagation into the transformer, that is in the inherent transformer attenuation. This attenuation should be expected to vary depending on the size and type of transformer.

REFERENCE

1. See reference 13 of the paper.

D. D. MacCarthy (General Electric Company, Pittsfield, Mass.): This paper reports the results of an extensive study of the effect of lightning-arrester lead length on the voltage at the terminals of the protected apparatus. In the past this subject has not received the attention that it deserves.

Figure 16 and Table III of the paper show the separation permissible between a lightning arrester and a transformer in order that the short-duration oscillatory voltage at the transformer does not exceed the voltage at the lightning arrester by more than 30 per cent under the specified conditions. These conditions include: a lightning arrester discharge current of 5,000 amperes crest rising at an effective rate of 5,720 amperes per microsecond; a single overhead line that terminates at the transformer; and a lightning arrester connected in "V." The authors have chosen a lightning arrester discharge current and the basic circuit as being representative of conditions that give high voltages at the transformer but which might

occur in service. A limit of 30 per cent overvoltage at the transformer was selected as a voltage of short duration that preserves the same margin of protection below the transformer strength as exists at longer values of time between the discharge voltage of the lightning arrester and the strength of the transformer demonstrated by American Standards Association tests. The "V" connection was selected since it is the best connection for minimizing the effect of the lightning-arrester leads.

However, power transformers have operated satisfactorily for years with the lightning arresters connected in "T," with longer lightning-arrester lead lengths, and with separations many times larger than shown in Figure 16. There are several factors that account for the excellent operating record of these transformers even though the margins of protection were less than they would have been had the practices recommended in this paper been followed. Lightning-arrester discharge currents rising as fast as 5000 amperes per microsecond are probably rare, although available data are few. In service the circuits are usually more complex than the basic circuit for which Figure 16 applies. More than one line is usually connected to the transformer bus. The capacitance of the bus is usually greater than that provided by a single transformer, and this also may reduce the voltage of the transformer.

Another factor that will reduce the voltage at the transformer is the presence of a charge on the transformer capacitance at the instant of lightning arrester gap spark-over. While Figure 16 indicates a separation of 9 feet between the transformer and a V-connected lightning arrester for a 115-kv circuit, this is for no charge on the capacitor and it is well to consider other data in the paper on the effect of capacitance charge. By allowing for the effect of a charge on the transformer capacitance, the lightning arrester and the transformer may be separated by 50 feet using the data in the paper. The effect of this charge is discussed in the paper and is shown in Figures 4 and 5.

The effect of charge on the voltage at a 115-kv transformer is illustrated by an example calculated from Figure 4 using these circuit constants:

"T" connection of 8-unit lightning arrester
Lead length (l) = 20 feet
Separation (D) = 50 feet
Capacitance (C) = 1,000 micromicrofarads

These calculations are shown in Table I of the discussion.

If the transformer capacitance is charged to 400 kv, the oscillatory voltage allowing for damping is 90 kv, which is only 83 per cent of the value permissible. Under this assumption, it is permissible to connect the lightning arrester in "T," with a lightning-arrester lead of 20 feet and a separation of 50 feet. However, if no initial charge exists on the transformer capacitance, the oscillatory voltage is 234 kv, which is 217 per cent of the permissible value. Hence, it is clear that the permissible lead length greatly depends upon the charge on the transformer capacitance. It would be helpful if the authors would present data similar to that in Figure 16, indicating recommended maximum separations between transformers and lightning arresters for both the T- and V-connections, assuming reasonable values of capacitor charge.

R. L. Witzke and **T. J. Bliss** (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The general method of analysis used in the paper involves a number of assumptions that limit greatly the value and applicability of the results. The separation distances between the lightning arrester and the transformer appear to be unrealistic and are not substantiated by field experience.

The studies reported were made by considering the conditions only after the lightning arrester starts to conduct current. This makes it necessary to neglect the initial charge on the capacitor used to represent the transformer, or to assign some arbitrary value to the initial charge. This charge has a very important influence on the voltage at the transformer as is evident from Figures 4 and 5 of the paper.

In our investigation[1] we assumed an incoming voltage surge having a constant rate of rise. The voltage at the lightning-arrester location was permitted to increase to a value corresponding to the lightning-arrester voltage before the elements used to represent the lightning arrester were connected to the circuit. This procedure gives due consideration to the transients before the lightning arrester gap operates, and does not require an assumption relative to the initial charge on the capacitor used to represent the transformer.

The incoming-line surge impedance has an important influence on the circuit voltages in those cases where reflections return from the transformer to the lightning-arrester location before the lightning arrester gap operates. It is therefore necessary to represent this circuit element in any complete investigation.

In problems of the nature reported in this paper, which involve a number of probabilities, misleading conclusions are reached if all assumptions are conservative. The assumptions of 5,000 amperes per microsecond in the lightning arrester, a plus $6^3/_4$ per cent lightning arrester tolerance and a 20 per cent margin lead to unrealistic separation distances.

1. CO-ORDINATION OF LIGHTNING ARRESTER LOCATION WITH TRANSFORMER INSULATION LEVEL, R. L. Witzke, T. J. Bliss. *AIEE Transactions*, volume 69, part II, 1950, pages 964-75.

T. J. Carpenter, I. B. Johnson, and **L. R. Saline:** It should be emphasized that these comments are primarily based on evaluating the over-all lightning arrester protective scheme in relation to the reduced insulation concept in voltage classes 115 kv and above. Specifically, the voltage classes, lightning arrester ratings, and the corresponding BIL values upon which the lightning arrester study was made are shown in Table II of this discussion.

The authors are in agreement with Mr. Meador's comments that more complete and more accurate statistical field data are required at the voltage levels studied on the rates of rise of voltage surges entering stations and on the rates of current rise through lightning arresters before a more accurate appraisal of proper lightning-arrester location can be made. Also such data should be evaluated in terms of the degree of shielding of both the station and the line, of the insulation level of the line and of the effect of the station configuration. Consequently, in considering costly equipment using reduced insulation, the authors felt justified in being conservative in the evaluation of the necessary assumptions.

Also, in Mr. Meador's discussion a request is made for lightning arrester separation as a function of capacitor charge at the time of lightning arrester sparkover. The results of the study indicated, with zero lightning arrester lead length (that is, with a V-connection), the permissible separations were 50 feet or more when the initial charge on the capacitor, at the time of lightning-arrester sparkover, was approximately equal to the lightning-arrester sparkover voltage; as contrasted to separations given in Table III of the paper for the same conditions but with zero initial capacitor charge on the capacitor.

As presumed by Mr. Opsahl a margin has been assumed between the voltage limited by the lightning arrester and the BIL level of the protected transformer in deriving the separations recorded in Table III of the paper. The BIL values chosen were reduced insulation values corresponding to those given in Table II of this discussion. One of the primary arguments for providing margin is to allow for the multishot strength of the transformer. Since some transformers fail as a result of a single impulse during the factory test, transformers which do not fail do not necessarily have additional strength to enable them to withstand a large number of impulses. Consequently, to assure a multishot strength for all transformers, some margin is necessary between

Table I

Initial Charge on Capacitance	1.25 PU	0
Capacitance voltage	1.5×8×40 = 480 kv	2.1×8×40 = 672 kv
Voltage across lightning arrester	8×45 = 360 kv	8×45 = 360 kv
Oscillatory voltage	120 kv	312 kv
75 per cent of oscillatory voltage	90 kv	234 kv
Permissible oscillatory voltage	0.30×360 = 108 kv	108 kv

Table II

System Voltage Level, Kv	Lightning Arrester Rating, Kv	BIL 1.5×40 Voltage Value, Kv
115	96	450
138	117	550
161	135	650
230	180	825
285	228	1050

the protective level and the demonstrated strength of the transformer.

The authors wish to reiterate some of Mr. McMorris' comments that the operator who desires to obtain the widest possible margin of protection should, ideally, approach the V-connection and the minimum possible separation between lightning arresters and transformers.

Mr. Beck comments on the results of our paper and the comparable results from a similar paper by Witzke and Bliss[1] and concludes they are not in agreement. However, as it will be shown later, the results from the two studies are not as different as it first may appear.

With regard to Mr. Beck's questions on our assumptions as related to field experience we wish to make several comments. First, the events preceding sparkover were not neglected, the effect being included as an initial charge on the capacitor or transformer at the instant of lightning-arrester sparkover. The effect of this initial charge is illustrated in Figures 4 and 5 of the paper. However, in setting up Table III of the paper the initial charge was set equal to zero, introducing a conservative assumption, perhaps, for most cases in view of the limited field data available. Second, with regard to rates of rise of lightning-arrester discharge currents and lightning-arrester discharge voltages, the lightning-arrester discharge voltage should initially rise almost instantaneously in response to the voltage already existing at the lightning arrester to cause sparkover. Similarly, if it is assumed that the circuit elements in the discharge path are entirely resistive, the initial rate of rise of lightning-arrester discharge current should be almost instantaneous at the time of lightning-arrester sparkover.

Further, from conclusions 3 and 6 of reference number 2 of this discussion of a field study, it is indicated:

1. That the wave shapes of lightning-arrester discharge currents were of the same general character as for direct strokes but with the fronts times to half value and durations markedly shorter.
2. That the wave fronts of lightning-arrester discharge currents are characterized by an initial high rate of rise as the lightning arrester starts to discharge.
3. That surge voltage values at the transformer were measured as large as 32 per cent greater than at the lightning arrester for the same surge.

Also, from reference number 3 of this discussion on lightning-arrester discharge currents in 132-kv stations, we wish to quote the following: "Although the maximum value of lightning arrester current measured in this investigation was only 4,100 amperes, on another part of the system a maximum lightning arrester current of 16,000 amperes was measured in an arrester on the 132-kv system—the result of a stroke within 400 feet of the station."

The 16,000-ampere lightning-arrester discharge occurred on a line and station that was shielded. Since the distance between the lightning arrester and the stroke makes it possible to consider it almost a direct stroke phenomena it is feasible that the effective rate of rise of the lightning-arrester discharge current exceeded that assumed in our study. The analysis given in the discussion of reference number 3 by Mr. Hagenguth would tend to support this possibility.

Mr. Hagenguth's discussion on the effect of many incoming lines and extended station bus substantiate in general a similar study on station configuration as recorded in the section on System Configuration of our paper. The effect of surges entering a station from a transmission line is decreased as the number of lines and number of pieces of apparatus is increased.

Mr. Finzi points to an accurate evaluation of the various sinks of energy in the equivalent circuit as most essential. This depends on complete and accurate lightning discharge data to begin with. With regard to the energy sink represented by the transformers, it was found experimentally for a number of transformers of different sizes that a transformer can be represented by a lumped capacitance as far as natural oscillations are concerned but the first crest of the oscillation of the voltage at the transformer is approximately 25 per cent less than that obtained with an equivalent capacitor substituted for the transformer. Also, for a transformer, the decay of the oscillations is almost complete in the order of 3 to 4 cycles.

In Mr. MacCarthy's comments on past satisfactory operation of power transformers with relatively long lead lengths and separations we wish to emphasize again that we are primarily concerned with transformers with reduced insulation with which there is limited field experience. We agree with Mr. MacCarthy's interesting discussion on the effect of the initial charge on the capacitor. At these higher voltages relatively long increases in lightning arrester lead length result in relatively small increases in voltage at the protected transformer.

R. L. Witzke and T. J. Bliss state that "The separation distances between the lightning arrester and the transformer appear to be unrealistic and are not substantiated by field experience."

Let us look at the record from an operator's point of view and experience, keeping in mind that we are discussing reduced insulation transformers only. Thus, from reference number 4 we quote:

"This resulted, in 1934, in adopting the so-called reduced insulation on a 30,000-kva 132-kv transformer bank where a lightning arrester of reduced rating was mounted directly on the transformer bank. (See Figure 9.) In this way, it was possible to use 115-kv class insulation for the transformers and a 75 per cent lightning arrester on our 132-kv grounded neutral system with an over-all saving in the order of 15 to 20 per cent. This practice has been continued up to the present time with complete transformer protection and entire satisfaction.

During the last 16 years, there have been installed on the American Gas and Electric Company system, nearly 3,750,000 kva of transformer capacity in the range of 88, 132, and 154 kv, all having reduced insulation—that is, one level below the standard BIL values. 180,000 kva has been on 154-kv lines, over 40,000 kva on 88-kv lines, and approximately 3,500,000 kva on 132-kv system."

Again, from Mr. Gross' closing discussion in reference number 2 it is stated that failure of station equipment is intolerable even though it may be the result of a possible infrequent high voltage at the transformer exceeding the voltage held by the lightning arrester.

And again from Mr. Sporn's discussion in this same reference number 2 it is stated that some 13 years prior to 1947 there was placed in service on the 132-kv system a transformer with closely coupled lightning arresters, the lightning arresters being mounted directly on the transformer tank and that the practice of closely coupling lightning arresters to equipment is now standard practice in this company. It is also stated that it seemed proper protection involves three important elements:

"1. Knowledge of the insulation strength of the transformer.

"2. Knowledge of the lightning arrester protective level.

"3. A relationship between the two to allow an appropriate margin between them."

In the comparable separations given by Witzke and Bliss for reduced insulation transformers and zero lightning arrester lead length, Table III of reference 1 shows separations of 53, 67, 92, 69, and 80 feet for system voltages of 115, 138, 161, 230, and 287 kv, respectively. These are to be compared with the separations recorded in Table III of our paper. One of the differences in assumptions in these results was the allowance of margin or no margin between the over-voltage appearing at the transformer due to separation and its equivalent voltage on the volt-time curve of the transformer insulation. Whereas it appears Witzke and Bliss have assumed no margin, we in our study have assumed some margin as necessary. Consequently, if instead of holding the oscillatory overshoot at the transformer due to separation to 30 per cent it is allowed to reach 50 per cent, then the lightning-arrester separations at 115 kv, 138 kv, and 161 kv become 55 feet, 65 feet, and 100 feet, respectively. These are to be compared with 53 feet, 67 feet, and 92 feet from the results by Witzke and Bliss which include the length of the down lead from the overhead line to the transformer whereas our separations do not.

We cannot agree with some of the statements made by Witzke and Bliss in the second paragraph of their discussion. Our study considered the conditions not only during and after lightning-arrester sparkover but those preceding it. It was not necessary nor was it done to neglect the initial charge on the capacitor used to represent the transformer. It is not necessary to arbitrarily assign a value to the initial charge. Our lumped circuit method of analysis is a simple approach in which the initial conditions at the time of lightning-arrester operation can be accurately calculated from assumptions pertaining to the rate of rise of the surge voltage causing lightning-arrester sparkover.

COMMUNICATION channels, for transmitting the various types of intelligence necessary for operation of a power system, are becoming increasingly important to the utility industry because of the trend toward centralized system control. Pilot wire and power line carrier channels are already used widely to accommodate the many items of information necessary for efficient system operation. Microwave channels are the most recent addition to the means of communication available for this purpose.

A microwave channel[1] is a beamed high-frequency radio communication medium which can be used to transmit from point-to-point the intelligence required in the normal operation of a power system. Relaying, telemetering, supervisory control, and voice communication are some of the functions which can use such a channel. The large number of items of information which can be transmitted simultaneously over a microwave channel makes it particularly valuable at locations where communication traffic is heavy.

It is the purpose of this paper to describe an experimental installation of a microwave channel and terminal equipment which accommodate simultaneously three voice conversations, two different types of protective relaying, two telemetered quantities, and supervisory control of eight points. A feature of considerable interest on this installation is the use of a reflector to provide a continuous path for the microwave beam between the terminal stations, where line of sight was not available. The use of the reflector eliminated the need for $2^1/_4$ miles of cable originally planned to connect one of the terminal stations to a point where line of sight to the other station was possible.

The installation is on the system of the Pennsylvania Electric Company and ties together the main generating plant at Seward and the operating headquarters at Johnstown, Pa. A joint test program has been carried out during the past year by the Pennsylvania Electric Company and the Westinghouse Electric Corporation.

The Problem

The Seward Generating Plant is the terminus for power line carrier communications, telemetering, and supervisory control equipment for the entire power system. The efficient operation of the system depends on adequate and reliable communication facilities between the system operator in Johnstown, approximately 12 miles distant, and the Seward Plant. The use of wire lines in the past has not been satisfactory because of outages and inferior service caused by extreme conditions, such as landslides, icing, automobile accidents, and gunshots.

The problem, therefore, was to prove that microwave and audio multiplex equipment provides a reliable channel which is suitable for voice communications, telemetering, supervisory control, and relaying.

It was decided that three 2-way telephone circuits, two 1-way telemetering circuits, one 2-way supervisory control circuit, and two relaying circuits would be provided for in the tests.

The Equipment Used

A block diagram of the equipment located at each terminal is shown in Figure 1. The microwave equipment and audio multiplex equipment are suitable for transmitting four voice frequency channels in each direction. Three of these channels are used for the telephone circuits and the fourth circuit has a number of tones applied to it which are keyed to perform the other functions. The microwave equipment and audio multiplex equipment, Figure 2, provide the means for the simultaneous handling of the circuits required by the various functions being used in the field tests. The microwave transmitters and receivers with the associated antennas and the reflector provide a radio beam capable of modulation over a band of about 30 kc. The multiplex equipment divides this broad band into several narrow bands by a system of frequency division. Each of these narrow bands can be used as a separate communication circuit and all can be used simultaneously. The equipment shown in Figure 2 provides four such bands, but is capable of being extended to seven. Each band can be further subdivided by the use of audio frequency tones to handle telegraphic types of service. The microwave and multiplex equipment is described in more detail in reference 2 of the bibliography.

Relaying

The directional-comparison-distance type[5,6] and the phase-comparison type[8] of "carrier" relaying are both used in this installation. The distance-type relays are connected to protect one of a pair of parallel 25-kv lines between Seward Generating Station and Broad Street Substation, and the phase-comparison relays are connected to protect the other. The Broad Street Substation is located

The telemetering transmitters are located at Seward and the receivers are at Johnstown

Figure 3 (right). Block diagram of the components to obtain the communication facilities required by a directional comparison, distance type of "carrier" relaying over a microwave channel. Note that under normal system conditions, a continuous blocking signal is present. The relaying equipment operates to "stop" the blocking signal on the occurrence of an internal fault

remote from the microwave equipment; therefore, the control circuits between the relays and the multiplex equipment are carried on underground control wires. In each case the signals required by the relaying system are transmitted and received on audio tones operating in conjunction with one of the subcarriers in the audio multiplex equipment, and the subcarriers in turn operating the microwave transmitter-receiver.

The units involved for the directional-comparison-distance type of carrier relaying are shown in block diagram in Figure 3. In this case the audio tone is transmitted continuously during normal power system conditions thereby providing continuous restraint on the receiver relay. The phase and ground relays are arranged to stop the tone transmission on the occurrence of an internal fault. This is the equivalent of a "continuous" carrier scheme as contrasted with the "intermittent" carrier scheme used in conventional carrier relaying applications. A means of continuous supervision of the channel for transmitting signals required by the relays is provided by this method of operation. The transmission of a continuous signal also eliminates the necessity for the relays to start a blocking signal on external faults, and it is therefore, not necessary to set the third zone of the distance relays to "look out" of the protected line section as required of an intermittent carrier scheme. Loss of the blocking signal under normal system conditions would not result in an incorrect tripout, as the phase and ground relays supervise tripping, and would not operate unless a fault existed on the system within their setting range. Backup tripping for phase faults is included in the phase relays. Backup ground relays were not provided for the test.

The phase-comparison system of relaying,[8] when used over a microwave channel is shown in the block diagram of Figure 4. The signals required by this relaying system also are handled on an audio tone. Since this is an

Figure 2. The microwave and multiplex equipment and the power supply components at Seward Generating Station. The two left-hand cabinets contain the audio-tone equipment, the next cabinet contains hybrids and signalling equipment, the next contains the frequency division equipment, and the cabinet on the right contains the microwave transmitter, receiver, and power supply units

Figure 4. Block diagram of the components to obtain the communication facilities required by a phase-comparison type of "carrier" relaying over a microwave channel. This is an intermittent system with the relaying intelligence, being carried over a 2,900-cycle audio-tone channel

"intermittent" carrier system, signals are transmitted only when a fault occurs on the power system. In addition, the blocks of "carrier" required for operation of this system must be transmitted at the power frequency. To accommodate this keying speed, a 2,900-cycle tone is used, and the control of this tone by the relays is through an isolating amplifier. Using this relatively low frequency to carry the relaying signals, resulted in a phase shift of about 55 degrees (60-cycle-per-second basis) in the received blocking signal and required the use of a delay filter in the circuit controlling the operating voltage of the relay. In other words, on an external fault, the half cycle block of "carrier" initiated at one end of the protected line to block the opposite end from tripping, after going through the receiving equipment would be 55 degrees behind the half cycle block of operating energy and depending on the phase position of the fault currents. This 55-degree shift could result in an incorrect operation on either an internal or an external fault.

Proper co-ordination of the relays for both the directional-comparison and phase-comparison systems using audio tones as the means of transmitting the necessary intelligence has been thoroughly checked on an artificial transmission line in the laboratory. Confirmation of these results is expected in the field experience which will be gained from this installation.

Staged fault tests are being planned to check the performance of the relaying equipments.

The two sets of relays for protecting one end of the two 25-kv lines are mounted on a common panel, Figure 5, along with the conventional-impulse-rate type of telemetering transmitter. A transmitter for an experimental frequency-type telemetering system is mounted on the rear of the panel.

Telemetering

Impulse-rate (frequency) type telemetering,[6,7] of two kinds is used in the trial installation. The impulse-rate type telemeter operating over a range of 40 to 200 impulses per minute is one kind, and an experimental electronic impulse rate (or frequency) system operating over a range of from 600 to 1,200 impulses per minute (10 to 20 cycles per second) is the other kind. As shown in Figure 1, the former is operating over a 560-cycle audio-tone channel, and the latter over a 1,080-cycle channel. The telemetering transmitters key the audio tone transmitters, and the telemetering receivers are fed from the audio tone receivers. Both transmitters are located at Seward Generating Station and the receivers are at Johnstown.

Supervisory Control

Two types of supervisory control systems[8,9,10,11,12] are used in this trial installation. One is the standard Visicode system and the other is the revertive pulse type as described in reference 12. Both are all-relay systems which provide for the control of any required number of individual pieces of equipment. The relays originate and receive impulses in coded groups to select the equipment to be controlled, to perform the operation, and provide an indication that the operation has taken place. Indications are also provided in the event of automatic operation of equipment.

One of the actual equipments used is shown in Figure 6, and consists of an 8-point assembly. This unit is used to control six 25-kv circuit breakers at Seward and to provide telemetering of a-c volts and a-c amperes from Seward to the dispatcher's office. Reference to Figure 1 shows the supervisory control equipment operating over 1,500- and 2,085-cycles-per-second audio-tone channels. In general, any tone frequency within the audio spectrum may be used; however, the speed of pulsing may make some frequencies at the lower end of the band undesirable.

Supervisory control has been used previously in conjunction with microwave equipment on an experimental installation made in 1943 on a frequency of 53 megacycles.[3] In this installation direct keying of the high frequency was used, as contrasted with the use of an audio tone channel working through audio multiplex equipment in the present installation.

Selection of Microwave Antenna Sites

The selection of antenna sites required considerable study, since microwave equipment requires a line-of-sight transmission path from the transmitting antenna to the receiving antenna. In addition, in order to eliminate serious fading the line-of-sight path should clear all obstacles by at least 50 feet. The topography between Johnstown and Seward showed that the line-of-sight path between the system operations office and the Seward plant goes about 1,000 feet underground. This ruled out the use of a direct path between the two points. Study of the terrain and charts indicated that a line-of-sight path did exist from a 200-foot tower at the Hilltop Substation near Johnstown (Figure 7) to a property at Armagh which was about $2^1/_2$ miles from the Seward plant. Further investigation of maps and terrain located a relatively inaccessible knoll which had line-of-sight paths to both Hilltop and the Seward plant. A repeater station located at this point would have satisfactory path clearance to both terminals. However, the lack of an available source of power, and inaccessibility of this location in bad weather led to the consideration of a reflector instead of an electronic repeater. Since there was no previous information available upon which to base a decision as to the practicability of the reflector, a mathematical analysis and field test program were laid out to prove the application.

Mathematical Analysis of Transmission Loss

The free space transmission loss of microwave energy over a given path can be calculated from formulas[13] derived to determine the maximum range over which a signal of a certain strength could be received from a transmitter of a given

power. For convenience these formulas have been rearranged as follows:

$$\text{Free space transmission} = 10 \log_{10} \frac{P_T}{P_R} \quad (1)$$

where

$$\frac{P_T}{P_R} = \left(\frac{4\pi R_0}{\sqrt{G_T G_R}\, \lambda} \right)^2 \quad (2)$$

and

$$G = \frac{4\pi A_{eff}}{\lambda^2} \quad (3)$$

where transmitting and receiving antennas are identical, equation 2 reduces to

$$\frac{P_T}{P_R} = \left(\frac{4\pi R_0}{G\lambda} \right)^2 \quad (4)$$

where

P_T = transmitter power in watts
P_R = received power in watts
R_0 = distance between antennas in meters
G_T = gain of transmitting antenna
G_R = gain of receiving antenna
λ = wavelength in meters
G = antenna gain
A_{eff} = approximately one-half of the projected area of the antenna in square meters

The total loss between a transmitter output and a receiver input includes other factors in addition to the free space transmission loss. In planning an application, allowance must be made for fading and also transmission line (in this case coaxial cable) losses between the equipment and the antennas.

The amount of fading that can be expected is a function not only of the amount of clearance obtained along the transmission path, but also of the weather. Fading is most severe during the summer months. Based on data previously taken[14] a fading loss figure of 1/2 decibel per mile is used for planning 940-to-960-megacycle installations, and this much fading is expected to occur only 1 per cent of the time. Transmission line (coaxial cable or the equivalent) loss depends on the type of transmission line and its length. The total loss for a given installation can be predicted by adding: the free space transmission loss; the fading loss; and the transmission line loss. For example, assume two 950-megacycle equipments with 42-inch diameter antennas located 20 miles apart, having a line-of-sight path with 50-foot clearance over all obstacles, 100 feet of transmission line at each terminal using *RG-17/U* coaxial cable. The following maximum attenuation would exist:

	Decibels
Free space transmission loss	87.1
Fading loss 20 miles × 1/2 db/mile	10.0
Transmission line loss	8.0
	105.1

Figure 5 (left). Switchboard panel at the Seward Station on which the relays for the distance-type and phase-comparison type of carrier relaying are mounted. A conventional impulse rate telemeter transmitter is mounted at the lower left, and an experimental electronic telemeter transmitter is mounted on the rear of the panel

Figure 6 (below). Supervisory control equipment located in the Seward Generating Station. Dispatching equipment of similar appearance is located at Hilltop Substation. Six circuit breaker control stations and two telemetering points are being used

Figure 7 (right). The 200-foot high frequency-modulation radio tower at Hilltop Substation, showing the microwave transmitting and receiving antennas mounted about three quarters of the way up

Figure 8. A comparison of the measured and calculated path attenuation between Armagh and Hilltop. The distance is 11.3 miles, frequency 955.5 megacycles, and the antenna gain 58. Levels above the zero line represents lower losses than the calculated values

Figure 10. The temporary reflector at Armagh used to check the calculations. The dish antenna on the left-hand pole was used in obtaining the data for Figure 8. The garage at the left was used to house the terminal equipment, and a temporary power line was constructed to supply the power for the equipment

These losses can be decreased by any or all of the following:

1. Increasing size of antennas, 2. Using lower loss transmission line. 3. Mounting the equipment closer to the antennas.

Where the loss between two terminals exceeds the permissible ratio between transmitter power output and minimum receiver input power, the transmitter output power can be increased or repeater stations installed. Where no line-of-sight path exists, reflectors can be used if the additional loss caused by the reflection does not increase the path loss beyond the maximum permissible attenuation for the equipment being used.

The increase in path transmission loss caused by the use of reflectors also can be calculated. In making calculations involving the use of reflectors, it is assumed that a plane reflector acts in the same manner as two parabolic antennas having areas equivalent to the projected area of the reflector in the two directions. The path loss can then be calculated by applying equation 2 twice: first, between the transmitter and the reflector to determine the equivalent amount of energy received at the reflector; and second, between the reflector and the receiver assuming that the reflector acts as a transmitter.

For a single reflector, equation 2 can be expanded to give directly the ratio of transmitter power to receiver input power as follows

$$\frac{P_T}{P_R} = \left(\frac{16\pi^2 R_1 R_2}{\sqrt{G_1 G_2 G_3 G_4}\,\lambda^2}\right)^2 \qquad (5)$$

where

R_1 = distance from transmitter to reflector in meters
R_2 = distance from reflector to receiver in meters
G_1 = gain of transmitting antenna
G_2 = equivalent gain of reflector in direction of transmitter
G_3 = equivalent gain of reflector in direction of receiver
G_4 = gain of receiving antennas
λ = wavelength in meters

The foregoing equations were used to calculate the expected loss with a reflector between Hilltop and Seward. From equation 5 the loss was calculated to be 115 decibels. This corresponds to the zero levels shown in Figure 8. The calculations also showed that a 20-foot square reflector would be required to meet this figure of 115 decibels. This would provide adequate margin of safety over the permissible path loss of 125 decibels with the type of microwave equipment being used. However, before proceeding with

Figure 9. A view from the temporary reflector location at Armagh looking toward Hilltop substation. The tower in Figure 7 is at the center of the notch between the two hills in the center background. The permanent reflector is shown

Figure 11. The permanent reflector. This is a rear view of the reflector looking toward the Hilltop Substation. This design is capable of withstanding 100-mile-per-hour winds or 60-mile-per-hour winds with ice coating which closes the perforations in the reflecting surface

a permanent installation of a reflector, it was decided that a test program would be carried out to determine the variation in signal strength at the reflector location, and try out a temporary reflector 20-feet square to check the calculations.

A microwave transmitter-receiver assembly was installed at Hilltop Substation and another at Armagh with recording voltmeters indicating received signal strength at Hilltop. Continuous recordings of field strength were made for a 6-week period. These data were converted into terms of the total attenuation between transmitter output and receiver input and an analysis made taking readings once an hour for the period.

A comparison between the measured data and the transmission loss calculated from the foregoing equations was made using measured values for coaxial cable losses. The following conclusions were reached:

1. That the measured path attenuation did not exceed the calculated data for more than 0.99 per cent of the hours during which data was taken. This calculated data included an allowance for fading of 1/2 decibel per mile of path.

2. That the measured path attenuation did not exceed the calculated data for more than 3.87 per cent of the time if no allowance is made in the calculated data for fading.

3. That although the maximum attenuation figures were not greater than would be expected from the calculations, the minimum attenuation figures were considerably less than would be expected.

The signal strength was found to vary considerably during a day. A plot of the hourly variation for several typical days during the test period is shown in Figure 8. The average level at the receiver was considerably greater than expected and fading about this average level was also greater than expected. The wide variations due to fading were attributed to multipath transmission of signals to the receiver, with alternate cancellation and reinforcement, possibly due to the terrain, Figure 9, as the several signals went in and out of phase.

Based on the calculated data it appeared feasible to use a reflector to get the signal to Seward, providing 6-foot diameter antennas were used at each terminal.

The first step in the reflector test program was to install a receiver and a 42-inch receiving antenna at Seward to determine if a signal reflected from natural surfaces was being received from Hilltop. In a series of tests made over a 2-day period, no measurable signal was received from any direction or at any polarization. Next a signal was transmitted from the Armagh transmitter and the signal level was checked at Seward. The measured loss was quite high indicating that line-of-sight did not exist, even though a study of the topographical maps had showed clear line-of-sight. It was decided, however, to install the temporary reflector, Figure 10, at Armagh and check the reflected signal level at two points on the highway where line-of-sight to the reflector could be obtained. This necessitated mounting the receiving equipment in a light truck equipped with a motor generator set so that readings could be taken at the side of the highway. The following results were obtained:

1. The measured beam width of the energy reflected from the screen was 2.4 degrees.

2. The total measured path attenuation to a point 2.75 miles away from the reflector (total path 14.05 miles) was approximately 115 decibels which is 10 decibels less than the maximum permissible with the type *FB* equipment.

3. Additional tests were made at a point 3.75 miles from the reflector where the maximum attenuation was approximately 133 decibels. Under these conditions voice

Figure 12. Topographical and contour map of the microwave path from Johnstown to Seward via the permanent reflector at Armagh. The location of the temporary reflector also is shown

communication over the circuit was very good, with slight noise in the background.

Based on the foregoing calculations and field data, it was decided to install a permanent reflector made of perforated sheet aluminum. This reflector is shown in Figure 11. It is mounted in a different location than the temporary reflector of Figure 10, and has a clear line-of-sight path to both Hilltop and Seward as shown in Figure 12. The tower support is 60 feet high and the center of the 20-foot square reflector is 50 feet from the ground. The reflector and tower are designed for use in 100-mile-per-hour winds and in 60-mile-per-hour winds with ice coating which close up the perforations. Because of the sharp beam of energy reflected from a surface of this size, it is of utmost importance that the reflector be positioned so a perpendicular to its center bisects both the vertical and horizontal angles subtended by the antennas at the terminal stations. For ease of this adjustment the reflector is mounted in gimbals, which permit it to be moved as much as ±10 degrees in both vertical and horizontal planes.

Results of Tests to Date

During the test period it has not been necessary to replace any tube on an emergency basis. No internal defects have developed such as a short circuit between tube elements or an open heater.

The experience to date on tube life is not conclusive; however, indications are that satisfactory life will be obtained. The microwave portion of the equipment has been operating continuously since February 1949, and replacement of tubes has been at about the same average rate as for power line carrier and mobile radio equipment. There have been no component failures. The multiplex equipment has been in operation since August 1949 with similar experience.

A direct lightning strike on the tower at Hilltop had no effect on the operation of the microwave equipment. Operation was not affected during the worst conditions of weather including heavy snow, sleet, and rain, indicating that sufficient margin of safety has been used. It is interesting to note that the maximum variation in path attenuation occurs on clear days in the morning and evening hours, and this is apparently the result of temperature inversion.

Data on noise and crosstalk, and distortion on the three telephone channels obtained by the microwave and the audio-multiplex equipment is given in Table I.

Table I

	Noise and Crosstalk, Decibels Below 1 Milliwatt	Distortion
Telephone channel Number 1	−41	Less than 1 per cent
Telephone channel Number 2	−40	Less than 1 per cent
Telephone channel Number 3	−43	Less than 1 per cent

The audio response of the three multiplexed channels is not over 6 decibels down from response at 1,000 cycles at 250 cycles and at 2,800 cycles.

Conclusions

The microwave and multiplex equipment have proved entirely satisfactory for service on power systems where reliability of performance is most important. Tube life in tests to date has been equivalent to that encountered in other electronic equipment used by power companies. As a result of the tests, plans are being made to permanently control the entire Seward Station switchyard from the load dispatcher's office at Johnstown using this microwave channel. When this is done a diesel-engine-driven generator will be provided at each terminal for emergency power.

The experience gained in the use of the reflector to provide a dog-leg path opens up an entirely new field of application possibilities for microwave channels. It is, however, desirable to check calculations and data taken from topographical maps by actual field measurements.

The type of reflector (powerless repeater) used in this installation eliminates the need for a power supply and therefore can be located in places which are physically difficult to get at.

The measured path losses were close enough to the calculated values to show that the formulas used are entirely practical for use in studying microwave applications.

Staged fault tests are planned to check the performance of the relaying equipment. Also the continuing test program anticipates a thorough check of the telemetering and supervisory control equipment.

The reliability of performance of the equipment on the tests opens up the possibility of using a microwave channel as the means of obtaining a transfer-trip type of protective relaying.

Discussion

R. H. Miller (Pacific Gas and Electric Company, San Francisco, Calif.): This paper is of particular interest due to the fact that it presents actual problems that were met in the establishment of a microwave communication system. The most unusual feature of the system described is the use of an inert repeater for completing a microwave path that does not provide line of sight. The successful use of this technique opens up many possible applications for such systems at locations that have previously been considered impracticable.

The microwave system discussed is very representative of the applications that are

of interest to power utilities in that voice, telemetering, supervisory control, and relaying channels were all provided.

The results of the tests, as discussed by the authors, indicate a high degree of reliability. The question is raised as to whether or not, where such a concentration of important communication and control channels are operated over a single link, duplicate microwave equipment with automatic transfer might be justified. It is also noted on Figure 8, the comparison of measured and calculated path attenuation that all of the data indicated was taken in a period of approximately one month. It would be of interest to know whether or not further measurements have been made to determine if there are seasonal variations in the microwave propagation properties.

O. A. Starcke (Kansas City Power and Light Company, Kansas City, Mo.): The authors are to be congratulated upon a concise yet complete report of a field test of a microwave channel. Present-day microwave theory, experience with similar multiple channels on carrier equipment, and laboratory tests of the microwave equipment itself, indicate that a multiple-use channel should operate successfully and reliably. The reasonably close check between the actual experimental results and calculated performance is a big boost in our confidence of our ability to forecast what microwaves will do in actual practice. However, since such an installation is expensive and the ultimate of reliability is required, it is believed that a test should be made of the transmission path before installation. It is believed that a test equipment of this nature could very easily be made available by the manufacturer for such testing purposes as a readily portable type of equipment.

The use of a reflector to cover a dog-leg path between the transmitter and receiver is an important contribution and should extend the use of microwave equipment considerably. It is particularly encouraging to find that the operation of such a reflector could be forecast with a reasonable degree of accuracy.

One of the great drawbacks to the rapid application of microwave equipment since the war has been the fact that military secrecy delayed or withheld the publication of the large amount of data accumulated on microwave transmission during the war years. The data is not always applicable since it was obtained primarily for predicting radar performance which usually depends upon the reception of reflected pulses of energy from various targets instead of direct reception of continuous waves. Publication of tests of the kind described in this paper will go far toward relieving the shortage of information on microwave operation.

D. R. Pattison: I wish to thank R. H. Miller and O. A. Starcke for their discussion of the subject paper. In closing this paper I would like to emphasize the following points:

Mr. Starcke comments on the lack of data on microwave performance. As he has pointed out, there has been very limited published data regarding the performance of microwave equipment. The data regarding the practical application of multichannel microwave equipment would no doubt be entirely different than that experienced by the radar application, primarily due to the wide band as applied in our communication application. Although the formulas used by us in our investigation have been published for quite some time, we still feel they are sufficiently accurate to predict actual performance.

I wish to emphasize the statement made in the paper regarding routing of microwave channels. Very little dependence can be put in United States geographic maps and actual line-of-sight survey should be carried out as suggested in the paper.

In answer to Mr. Miller's comment, we do believe that the reliability of such microwave channel does justify our reliance in such a system for the operation of this important equipment. We have considered the installation of duplicate equipment and the automatic transfer feature. However, to date we have not been able to justify it. Experience will eventually indicate whether the duplicate equipment is necessary or not.

It is true that our comparisons were taken over a period of approximately one month. However, we have made a continuous record of the channel performance. Although a distinct improvement has been made in the performance by the use of voltage regulation, larger dishes and proper focusing, the curves as shown on Figure 8 are fairly indicative. We are continuing to collect this data and no doubt it will be available to those who are interested.

Proposed Basic Impulse Insulation Levels for High-Voltage Systems

J. E. CLEM

W. J. RUDGE
MEMBER AIEE

A. H. POWELL
MEMBER AIEE

SINCE the establishment of basic impulse insulation levels (BIL)[1] there has been essentially no change in the values up to the present time. On the other hand, there have been improvements in the method of operating systems, increased knowledge of the lightning discharges, and better understanding of the surge behavior of apparatus and its insulation. Several industry committees are at present investigating the factors which determine the BIL. It is in the hope of successfully culminating a part of this work that this paper is being presented. Since the greatest need for a review in the industry at present is associated with the transmission voltages 115 kv and above, this paper is confined to the BIL applying to these voltages.

Object

The purpose of this paper is to make an evaluation of the essential factors upon which the selection of BIL can be based, and to propose a series of BIL for adoption by the industry, based upon these considerations.

The Factors

It generally is recognized that the principal factors to be evaluated in the establishment of BIL are: nominal system voltage; system neutral grounding; lightning-arrester rating and performance; lightning-arrester location and system arrangement; impulse strength of equipment; and required margin.

Nominal System Voltage

The Joint Edison Electric Institute–National Electrical Manufacturers Association Report on Preferred Voltage Ratings for A-C Systems and Equipment[2] gives the results of an industry survey of system operating practices and sets the nominal and maximum tolerable zone voltages. The maximum voltage of the tolerable zone was used as a basis for this study.

A review of the general problem of impulse insulation levels indicates that the circumstances and conditions pertaining to the required impulse insulation levels are different in the distribution range of voltages of 15 kv and below than in the subtransmission range of 15 kv to 69 kv inclusive, and that both of these are different than in the high-voltage transmission range of 115 kv and higher. In this paper only the high-voltage transmission range is considered.

System Neutral Grounding

Part II of Present-Day Grounding Practices on Power Systems[3] which covered a total of 567 systems, shows that of the companies reporting nearly 100 per cent of power systems 115 kv and above are operating with neutrals grounded and that 95 per cent of these are "effectively grounded" according to the commonly accepted definition.[5,12] In Table XIX of the report[3] it may be seen that for circuits rated 93 kv to 165 kv most systems have X_0/X_1 ratios less than three, although there are a few in which the ratio goes as high as four. Above 166 kv the systems have ratios ranging from zero to one. Of the effectively grounded systems having circuit voltages 93 kv and higher, only one had an R_0/X_1 ratio in excess of one, and that did not exceed a ratio of two. Since this is the practice, it is logical for standardization purposes to select lightning-arrester ratings based on grounded-neutral operation.

It may be necessary to use higher lightning-arrester ratings and insulation levels at nongrounded substations which may be removed from the grounded portion of the system.

Selection of Lightning-Arrester Rating

As is indicated in reference 3, for circuit voltages of 115, 138, and 161 kv the systems are effectively grounded, and hence the rating of the lightning arrester can be 80 per cent of the line-to-line voltage. For these systems the voltage on the two unfaulted phases will not rise over the line-to-neutral voltage for the case of single line-to-ground faults by more than 40 per cent. While this rise in voltage may be lowered in some cases where lightning arresters are located at the transformers, it should be recognized that for lightning arresters located on the line side of a circuit breaker in the open position the conditions may be such as to require the full 80-per cent rating for the lightning arrester. There may also be cases for which the full 80-per cent lightning-arrester rating is required for transformers. Hence, the 80-per cent lightning-arrester ratings were chosen for this study for systems operating at voltages of 115, 138, and 161 kv.

For system voltages of 230 kv and up, however, the X_0/X_1 and R_0/X_1 ratios are generally less than for the 115- to 161-kv range, and the overvoltages on the unfaulted phases will not, except in unusual cases, exceed 30 per cent of the line-to-

Paper 50-152, recommended by the AIEE Protective Devices Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 10, 1950; made available for printing April 17, 1950.

J. E. Clem is with the General Electric Company, Schenectady, N. Y., J. R. Meador and W. J. Rudge are with the General Electric Company, Pittsfield, Mass., and A. H. Powell is with the General Electric Company, in Philadelphia, Pa.

The authors are grateful for the permission of the Consumers Power Company, Jackson, Mich., to use the heretofore unpublished data on lightning arrester discharge currents included in Figure 1; for the assistance of S. B. Howard of the General Electric Company, Pittsfield, Mass., for the probability calculations in connection with lightning arrester performance; and to several others for their suggestions and comments.

neutral voltage. Therefore, it appears logical to select lightning-arrester ratings for these higher circuit voltages which are 75 per cent of the line-to-line voltage. For circuit breakers at these higher voltages it probably will be necessary to use an 80-per cent lightning arrester, particularly on the line side, although the transformer lightning arrester in the same station can be a 75-per cent one.

The following table of lightning-arrester ratings for the different systems was therefore selected on the basis of even multiples of 3 kv as the minimum increment of rating.

Table I

Preferred Nominal System Voltage, Kv	Maximum Tolerance Zone, Kv	Lightning-Arrester Rating, Kv: Non-grounded Neutral, 100 Per cent Lightning Arrester	Grounded Neutral, 80 Per cent Lightning Arrester	Grounded Neutral, 75 Per cent Lightning Arrester
115	121	120	96	
138	145	144	117	
161	169	168	135	
230	242	240	192	180
288	302	300	240	228
345	360	360	288	270
360	378	378	303	282

Lightning-Arrester Performance Values and Tolerances

At the request of AIEE Standards Co-ordinating Committee Number 8 (Insulation Co-ordination), the arrester manufacturers reviewed their production records to determine if it would be feasible to reduce the maximum tolerance of lightning-arrester performance as given in the report Performance Characteristics of Lightning Protective Devices.[4] The NEMA Lightning Protective Devices Committee, after reviewing the matter, replied that a review of the present-day manufacturing practice and performance values for station- and line-type lightning arresters has shown that the plus tolerances relating to impulse spark-over and discharge voltage drop in the resistance can be reduced by 5 per cent, as shown in Table II.

Table II

Type of Lightning Arrester		New Tolerance, Per cent	Present Tolerance,[4] Per cent
Station:	impulse spark-over	+15	±20
	discharge voltage drop	+10	±15
Line:	impulse spark-over	+20	±25
	discharge voltage drop	+15	±20

Note: These tolerances may also apply to the current wave later discussed in this paper.

In addition to the tolerances shown in Table II, the committee pointed out that approximately 95 per cent of the lightning arresters supplied have performance values which do not exceed the average plus two-thirds of the stated maximum tolerance.

The NEMA Committee recommended that the protective level of the lightning arrester be taken as a value which is the average value plus two-thirds of the stated maximum tolerance.

Lightning-Arrester Discharge Currents in Service

A review of the data obtained in several separate investigations[5,6,7,8] of discharge currents through lightning arresters in stations resulted in the average discharge expectancy curve shown in Figure 1. For the study reported in this paper a crest value of 5,000 amperes was chosen as a reasonable reference base. It will be noted that a discharge current exceeding this value will occur only once in about 70 lightning-arrester years.

A further review of the data from three separate investigations[6,7,9] giving the time-to-crest for currents discharged through lightning arresters in stations resulted in the average expectancy curve, Figure 2. The data did not show any direct or definite correlation to exist between the time-to-crest or rate-of-rise and the crest current, although it was noted that many of the fast rates-of-rise occurred with low crest values of current. The highest recorded rate-of-rise is approximately 5,000 amperes per microsecond[10] (10-per cent and 90-per cent points), and was associated with a crest current of 7,900 amperes. This data was obtained on a 23-kv system which had no ground wire shielding. It appears reasonable from the review of these data to use as the basis for this study a rate-of-rise of 5,000 amperes per microsecond, and to associate with this a crest value of 5,000 amperes. This gives a wave having an effective front of 1.0 microsecond, based on measurements of the time between the 10 and 90 per cent of crest value points.

This choice of 5,000 amperes and 5,000 amperes per microsecond presumes that the overhead line leading into the station, and the station itself, will be protected by overhead ground wires. The ground wires should extend for a distance of approximately $^1/_2$ mile from the station steel.

If it is assumed that the time-to-crest is 1.2 times the time of the effective front it may be seen from Figure 2 that a time-to-crest of 1.2 microseconds, or an effective front time of one microsecond, occurs once in five lightning-arrester years.

Separation Between Lightning Arrester and Transformer

The difference in the voltage at a transformer, or other protected equipment from the voltage at the lightning arrester, when there is some circuit distance between them, has been investigated in several studies.* An evaluation of the effect of the circuit distance is given in the paper by Carpenter, Johnson, and Saline;[11] since this subject is fully discussed there, it is not dealt with at length in this paper. The relation between the lightning-arrester protective levels and proposed BIL is based on using a V-connection, as defined in reference 11, and limiting the separation between the lightning arrester and protected equipment. The circuit distance, or separation, between the lightning arrester and the protected equipment may cause an oscillatory increase in the voltage at the protected equipment above the lightning-arrester discharge voltage. The limiting separations given later are

* See companion paper by Carpenter, Johnson and Saline,[11] and the references therein.

Figure 1. Discharge currents measured through lightning arresters in stations

chosen so that the crest value of the first cycle of the oscillatory voltage at the protected equipment does not exceed the lightning-arrester discharge voltage by more than 30 per cent. These limiting separations are considered representative of single line stations because the analysis upon which they are based considered only an elementary circuit configuration and did not include the effect of a bus or additional incoming lines.

Number and Magnitude of Surge Voltages Applied to Protected Equipment in Excess of the Base Voltage

If the discharge voltages of a station lightning arrester at 5,000 amperes per microsecond and various crest currents are compared with its impulse spark-over voltage (AIEE wave), using average performance values plus two-thirds of the industry maximum tolerances, it is found that the crest value of lightning-arrester discharge currents below 5,000 amperes will produce lightning-arrester discharge voltages less than the lightning-arrester spark-over voltage. Therefore, the maximum lightning-arrester discharge voltage for these discharges will be determined by the lightning-arrester spark-over voltage and will be independent of the crest value of the current.

Conversely, only currents in excess of 5,000-ampere crest will produce discharge voltages in excess of the lightning-arrester discharge voltage chosen for the basis of this study, or as it may be termed, the reference discharge voltage. It was felt that the probability of voltages in excess of the reference discharge voltage should be estimated so that the effect on equipment insulation could be studied. By combining the lightning-arrester volt-

Figure 3. Calculated impulse discharge voltage above reference lightning-arrester voltage at lightning arresters in stations

ampere characteristics with the lightning-arrester-discharge current expectancy curve of Figure 1, the expectancy curve of lightning-arrester discharge voltages shown in Figure 3 is obtained. This curve shows that only a limited number of the lightning-arrester discharge voltages will be above the reference lightning-arrester discharge voltage.

To determine the number of times that these higher voltages will occur at a given lightning arrester, a calculation was made assuming that the discharge current of 5,000 amperes, and the wave front of 5,000 amperes per microsecond, are concurrent and that all currents exceeding 5,000 amperes have the same rate-of-rise. There is no field data to substantiate this, and accordingly it is a very conservative assumption which places the calculated voltages above those expected in service.

For example: for such a calculation it is most convenient to consider a group of 100 single-pole lightning arresters operating over a period of 30 years, or 3,000 lightning-arrester years. From Figure 3 (0.015×3,000) or 45 of the discharges in this 30-year interval will cause discharge voltages higher than the reference lightning-arrester voltage.

Calculations were made to determine the proportional part of the total number of lightning arresters, 100, which might have one, two, or three current discharges during the 30-year period capable of producing a discharge voltage higher than the reference discharge voltage used in this study. The probability expression used is

$$P_m(n) = \frac{e^{-mp}(mp)^n}{n!}$$

where

$P_m(n)$ = probability of n discharges through one unit in m total discharges

m = number discharges (45 above reference lightning-arrester voltage)

$p = \dfrac{1}{\text{number lightning arresters}}$ (0.01 for this calculation)

The calculations show that 29 per cent of the lightning arresters will have one current discharge which will produce a lightning-arrester discharge voltage in excess of the reference lightning-arrester voltage; 6.5 per cent, two such discharges; and less than one per cent, three such discharges in the 30-year period.

The results of similar calculations for 105 per cent, 110 per cent, and so forth, of reference lightning-arrester voltage are shown in Figure 4. These curves show only one lightning arrester out of a hundred might be expected to have one discharge exceeding 114 per cent of the reference lightning-arrester voltage, or three exceeding 100 per cent, over the 30-year period. These factors are considered in selecting the margin later in the paper.

Figure 4. Probability of lightning-arrester discharge voltage exceeding reference lightning-arrester voltage in a 30-year period

Impulse Strength of Equipment

The American Standards Association impulse test on high-voltage transformers consists of a full (1.5×40) wave at BIL value and two waves at 15-per cent higher level chopped in not less than 3.0 microseconds.

A front-of-wave test sometimes is made to demonstrate the volt-time turn-up of the transformer insulation. Test results show[13] that the impulse puncture strength of the major insulation used in transformers is constant from about 3.0 microseconds to several hundred microseconds or more. For shorter times the impulse strength increases. At 0.5 microsecond the breakdown is about 50 per cent greater than 3.0 microseconds. This volt-time relationship, which has been used to determine the front-of-wave test for transformers in the NEMA Transformer Standards, is shown as Curve 1 in Figure 5.

Other parts of the transformer, such as oil spacings, creepage paths, and so forth, have other volt-time curves. However, the minimum envelope of these curves tends to follow a volt-time curve similar to Curve 2 in Figure 5. Thus, the over-all transformer volt-time curve can be represented best by a composite broken curve going from 0.5 microsecond to 3.0 microseconds along Curve 1, and from 3.0 microseconds to longer times along Curve 2. The plotted points represent the ASA full-wave and chopped-wave tests. The exact point along Curve 1 for showing the NEMA front-of-wave test depends on the insulation test level of the transformer, since this test is made with a voltage rising at approximately 1,000 kv per microsecond. All transformers designed to meet the ASA impulse tests are also designed for this front-of-wave test.

The impulse insulation strength of switchgear is usually checked, when required, by full-wave impulse withstand tests at BIL value. During the design and development of power circuit breakers, chopped-wave tests also are made. These tests are made at values 35 to 50 per cent above the full-wave withstand values. However, as switchgear equipment contains no windings, the magnitude of the test voltage is of more importance than the rate of change of the voltage wave.

Effect of Superimposed Frequency Oscillations on Transformer Insulation

Since the circuit separation between the lightning arrester and the transformer results in a high-frequency oscillation being superimposed upon the voltage wave which appears at the transformer terminals, it is necessary to determine the effect such a voltage would have on the transformer insulation. Since the superimposed oscillations are of very short duration, relative to the 1.5×40 microsecond test wave, it is apparent from Figure 5 that the Curve 1 portion of the transformer volt-time curve will be most affected by them. A few spot tests have indicated that insulations of the type represented by Curve 2 are not appreciably affected by them.

To get an estimate of the effect of these oscillations on transformer insulation, samples having a volt-time curve similar to Curve 1, Figure 5, were selected for these tests. These samples consisted of heavily-insulated conductors taped together and immersed in oil. When tested with smooth 1.5×40 waves the curve in Figure 6 was obtained. The similarity to Curve 1, Figure 5, is apparent.

Similar samples were tested with 1.5×40 (negative polarity) waves having damped superimposed high-frequency oscillations. There were three variables in

Figure 5 (below). Transformer volt-time curves

Figure 6 (right). Volt-time curve of insulation samples (1.5×40 negative polarity) representative of transformer major insulation

Figure 7. Representative voltage waves used for tests on insulation samples

addition to the magnitude of the 1.5×40 wave: a. period of oscillation; b. degree of damping; c. per cent "overshoot" of the oscillation. Typical voltage waves are shown in Figure 7. The test results are shown in Figure 8. The points are plotted to show how much, for equal severity on the insulation, the magnitude of the smooth 1.5×40 wave upon which the oscillations are superimposed must be reduced as the magnitude of the superimposed oscillation (overshoot) is increased. On the assumption that these insulation samples are reasonably representative of transformer major insulation, a significant conclusion can be drawn.

From Figure 5 it is apparent that transformer major insulation puncture strength will withstand a full wave at the chopped-wave level. The problem, then, is to determine what oscillations can be superimposed on the full wave at the BIL value to have the same destructive effect as a smooth full wave at the chopped-wave level. On Figure 8, the curve is drawn through the minimum points to be conservative. This curve goes through 87-per cent magnitude for a wave having 30-per cent overshoot. The conclusion is that a damped high-frequency oscillation, whose first crest is 30 per cent above the smooth wave, may be superimposed on the full wave without stressing the transformer major insulation to a greater extent than the ASA chopped wave, since the ASA full-wave test is 87 per cent of the chopped-wave test. For this reason the permissible separation between lightning arrester and transformer used in this selection of BIL was so chosen that the oscillation superimposed on the lightning-arrester voltage was limited to 30 per cent and therefore would not require the addition of any insulation to take care of it.

Table III gives the maximum separation which is permissible on this basis for the lightning-arrester ratings proposed. The method of arriving at these distances is given in reference 11, and the distances are based on the elementary circuit configuration.

Table III

Lightning-Arrester Rating, Kv rms	Number of 12-Kv Units	Maximum Separation, Feet
96	8.0	9
117	9.75	15
135	11.25	20
180	15.0	38
238	19.0	72

Ratio of Single to Multishot Strength of Transformer

It is necessary to evaluate the long-time strength of transformers that are periodically subjected to transient voltages. A carefully considered answer must weigh several factors, some of which are:

A. Laboratory investigations of the effect of repeated applications of impulse voltages are, of necessity, compressed into a relatively short period of time. A transformer in service may be subjected to only one or two high-impulse voltages in one year, thereby having long-time intervals to recover. Therefore, the ratios of single-to-multishot strength determined from laboratory test results probably are not directly indicative of the multistrength of the transformers when in service.

B. During factory impulse testing, transformers are sometimes subjected to many times the required number of impulse voltages and it is extremely rare for these additional applications of voltage to cause failure.

C. If a transformer being tested is near breakdown, this condition is often detectable by modern, sensitive testing technique.

These factors tend to deprecate the need for additional margin to allow for repeated application of voltage in service. However, a strong argument can be made for a multishot allowance. Since it is a known fact that some transformers fail as a result of a single impulse during the factory test, it cannot be said that the units which do not fail have an additional margin of strength to enable them to withstand a large number of impulses. Therefore, it is unreasonable to expect that all transformers passing the factory test have multishot strength. For this reason some margin is necessary between the protective level and the demonstrated strength of the transformer.

Reference Lightning-Arrester Discharge Voltage and Required Impulse Insulation Levels

Reference Lightning-Arrester Discharge Voltage

Since the published data on lightning-arrester performance are given on the basis of a 10×20 microsecond wave, it is necessary to use a correction factor to derive the lightning-arrester discharge voltage for a different wave shape. This point was brought up for discussion at the meeting of an AIEE Subcommittee of the Protective Devices Committee, and the manufacturers stated that the crest value of discharge voltage for a 5,000-ampere, 5,000-ampere-per-microsecond discharge current is approximately the same as the crest value of the discharge voltage for a 10,000-ampere 10 × 20 discharge current. On this basis the reference lightning-arrester discharge voltage, or protective level, for station-type lightning arresters of representative voltage ratings, on the basis of a 5,000-ampere discharge current, is as shown in Table IV.

Discharge voltages are for a current discharge having a crest value of 5,000 amperes. These values are shown on Curve A, Figure 9.

By using the method contained in ASA Standards Z1.1, Z1.2, and Z1.3[14,15,16] it can be shown that as lightning-arrester units are stacked in series the effective plus tolerance for the entire stack is decreased with the number of units in

Figure 8. Effect of superimposed oscillations on strength of insulation samples

the stack, and that the discharge voltage then is given by the equation

$$E_d = E_a N\left(1+\frac{0.067}{\sqrt{N}}\right)$$

where

E_d = Minimum reference lightning-arrester discharge voltage
= Minimum protective level

E_a = Average lightning-arrester discharge voltage given in the published data for a 12-kv rating

N = Number of 12-kv ratings connected in series

0.067 = Plus tolerance for one 12-kv rating

Therefore, the minimum reference lightning-arrester discharge voltage, protective level, is not a linear function of rating but has a slight curvature. Discharge voltages calculated from the formula are shown as Curve *B* on Figure 9. This curve was used in the determination of the minimum protective levels which the lightning arrester could be expected to provide. It should be noted that the Minimum Reference Lightning-Arrester Discharge Voltage or the synonomous Minimum Protective Level always includes the positive tolerance, and thus the meaning of the term "minimum" is by definition restricted accordingly.

Required Margin

When choosing the margins these factors should be considered:

A. The deviations in lightning-arrester performance.

B. Effect of separation between lightning arrester and protected equipment.

C. The single and multishot strength of equipment.

Table IV. Station-type Lightning Arresters

Lightning-Arrester Voltage Rating	Lightning-Arrester Discharge Voltage or Protective Level	
	10×20 Microsecond, Kv	5,000 Amperes Per Microsecond, Kv
12	43	47
96	345	373
120	430	467
240	860	931

D. Possible occurrence of impulse currents above 5,000 amperes and 5,000 amperes per microsecond.

The lightning-arrester manufacturers have made allowance for the deviations in lightning-arrester discharge voltages in recommending a protective level to be determined by adding a factor of two-thirds the plus tolerance to the average performance values. Therefore, it is felt that no additional margin is required to take care of this factor.

The superimposed oscillation in the voltage across the equipment being protected causes an increase in voltage above the protected level maintained by the lightning arrester. By imposing limits on the separation between the lightning arrester and the protected equipment this factor is adequately taken care of.

The transformer strength is demonstrated by two applications of a chopped-wave test, but sometimes several applications of the test are made before the test is completed. The transformer insulation strength may deteriorate in service due to the application of several high-voltage impulses. It is reasonable to provide some margin for these contingencies.

The probability of discharge currents through the lightning arrester exceeding 5,000 amperes also should be included in the margin.

It is not good engineering to pyramid the separate safety margins for each of the foregoing factors. Considering all of them together, it seems reasonable to use an over-all margin of 20 per cent above the protective level provided by the lightning arrester to establish the minimum required impulse insulation levels.

Curves *C* and *D* in Figure 9 were plotted at 20 per cent above the lightning-arrester discharge voltage shown by Curves *A* and *B*, respectively. Curve *D* evaluates the stacking factor and represents the minimum required impulse insulation levels obtained from this analysis.

Table V gives the required impulse insulation levels for systems with nominal system voltages 115 to 360 kv, using the lightning-arrester ratings from Table I.

During the preparation of Table V, these facts were brought out:

A. There are no preferred system voltages above 230 kv. However, there is a system already operating in this country at 288 kv (sometimes listed as 287.5 kv).

B. The system voltage of 360 kv is listed instead of 345 kv as in the BIL report[1] because it is the highest system voltage that can use the present standard BIL of 1,300 when operated as an effectively grounded system.

C. The standard BIL for the listed 345-kv reference class is 1,550 and the value of

Figure 9. Lightning-arrester discharge voltage and required insulation level versus lightning-arrester rating kilovolts rms

Figure 10. Proposed BIL values versus nominal system voltage

1,615 given for the 360-kv nominal system voltage is consistent with the present array of BIL.

Selection of BIL

The Effect of Small Changes in BIL Values on Transformer Design

It should be realized that the strength of insulation is not predictable to within two or three per cent. Turn insulation, spacings between coils, the thickness and number of insulating barriers, and so forth, cannot be changed in extremely small increments. A great deal of testing and experience is required to achieve just the right balance in these components for each BIL value. These components become standardized building blocks for the designer to use for a given BIL value even though practically all high-voltage transformers are purchased with ratings or characteristics which require different design layouts.

This standardization of the components used to secure a given BIL has contributed greatly to transformer reliability and lower cost by permitting repetitive use of certain insulation structures. It would require a long time and involve considerable expense to gain back the loss entailed in changing to new BIL which are only slightly different from those now in use.

Requirements for Ungrounded Installations

There may be occasions when transformers and circuit breakers supplied on systems 115 kv, 138 kv, and 161 kv may be called upon to operate on ungrounded neutral circuits. Accordingly, it is desirable to have levels suitable both for grounded-neutral system operation and also for isolated neutral operation for these circuit voltages. It is not anticipated that this requirement will exist for system voltages 230 kv and higher and, accordingly, only impulse insulation levels suitable for grounded neutral operation are required in this range.

Insulation Levels of Switchgear

Circuit Breakers

Power circuit breakers present different problems than do transformers when considering the problem of reducing their insulation, because the voltages at their terminals is not always subject to the same degree of control as those at transformer terminals.

Earlier in this paper it was pointed out that most systems operating at voltages 230 kv and higher are operated with their neutrals very well grounded. Circuit breakers with reduced insulation levels have been used successfully on these systems for a number of years. However, it is desirable to give further study to these systems.

Systems operating at 115, 138, and 161 kv are discussed as a group, since they represent additional special problems. It is noted that a large per cent of these systems are at times operated ungrounded, or so that the X_0/X_1 ratios are greater than 3.0. Loss of ground may also occur on the opening of some of the line circuit breakers. Thus a grounded-neutral rated lightning arrester could not, in these cases, be used to protect circuit breakers used on systems operating at 115, 138, and 161 kv.

In consideration of the various circuit conditions that may be present, and the desirability of retaining a margin in a circuit interrupting device, it is concluded that the circuit breaker must be capable of interrupting 87 per cent of its rated interrupting capacity at full line-to-line voltage. Therefore, the circuit-breaker interrupter would not be changed, and material reduction in circuit breaker or switch parts would be negligible and not justify the necessary new designs and additional ratings.

External Porcelain Insulation

The life of bushings and insulators which are used with circuit breakers, switches, bus supports, and so forth, probably will not be reduced by operating them at higher 60-cycle voltages than at present. Such a condition would result if the low frequency wet and dry withstand tests were reduced in the same proportion as the reduction in impulse levels.

However, creepage and strike distances over the exposed surface must be reviewed very carefully before reducing the size of these parts. The present values appear to be satisfactory, although wet flashover values have little margin and greater creepage has been required if excessive contamination is expected.

Air switches are designed with open gap distances which are at least 10 per cent greater than the insulator striking distance. A reduction in insulation could be reflected in reduced switch dimensions. However, the material savings would be

Table V

Nominal Circuit Voltage, Kv	Impulse Insulation Level: Isolated Neutral	Grounded, 80 Per Cent Lightning Arrester	Neutral, 75 Per Cent Lightning Arrester	Present BIL, Kv
115	540,562*	432,450*		550
138	645,675*	518,542*		650
161	750,788*	605,630*		750
230			810,850*	1,050
288			1,025,1062*	1,300
360			1,268,1331*	(1,615)

* The minimum value for the required impulse insulation level represents that which could be used if the lightning arrester was given full credit for the stacking factor. The larger value is obtained when the stacking factor is ignored completely.

small, and problems involving corona and radio noise would be amplified. Smaller open break distances would also reduce the isolating safety factor of the switch.

It is questionable if any reductions in the size of the external porcelain insulating part of equipment used on circuits operating at 115, 138, and 161 kv can be justified, even with effectively grounded neutrals.

It is concluded from the foregoing considerations that the impulse insulation levels for both circuit breakers and external porcelain insulating parts, including bus insulations, should be those associated with the use of the 100-per cent lightning arrester.

The Proposal

Based on the foregoing considerations and analysis, we propose that the values shown in Table VI be adopted as BIL for equipment used on systems operating at nominal voltages 115 kv and higher. These values are shown in Figure 10 and are on the basis of the standard 1.5×40 microsecond impulse voltage wave.

They have been determined on the basis that the circuit distance between the lightning arrester and the protected equipment will not exceed the maximum values shown in Table III.

Table VI

Nominal System Voltage, Kv Column 1	Isolated Neutral Circuit BIL, Kv Column 2	Grounded Neutral Circuit BIL, Kv Column 3
115	550	450*
138	650	550*
161	750	650*
230		†850**
288		1,050**
360		1,300**

Values in Column 2 are to be used for switchgear, and for transformers, if and when necessary.

* Values are to be used for transformers, not for switchgear.

† A lower value of 825 could be reasonably derived from this analysis by giving partial credit for the benefit of the stacking factor.

** Values are to be used for both switchgear and transformers.

Discussion

A. M. Opsahl (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The authors take a value of 43 kv as the lightning arrester discharge voltage or protected level on a 5,000-ampere 10x20-microsecond wave, and 47 kv on a 5,000-ampere-per-microsecond 5,000-ampere wave for a 12-kv lightning arrester. The kilovolt values are given without regard to time. I think this could be amplified. The valve lightning arrester characteristic is such that at crest discharge current the voltage is dropping. There is also another characteristic of valve lightning arresters that at high rates of rise of current, the discharge voltage reaches a higher crest. These two characteristics are tied together in the crest value and shape of the lightning-arrester discharge voltage during a surge test. The voltage crest is reached on the rise in current rather than at crest current so the rate of rise of current rather than its magnitude determines the voltage crest. For instance, a discharge current having a crest of 5,000 amperes and one having a crest of 20,000 amperes produce about the same discharge voltage crest across the lightning arrester if the rates of current rise in amperes per microsecond are the same. The 5,000-ampere 5,000-ampere-per-microsecond current wave has substantially the same rate of rise of current as the 20,000 ampere 10x20 wave and approximately the same crest voltage will be obtained in both cases.

The effect of steep front current waves on lightning-arrester discharge voltage was discussed at a Subcommittee meeting of the AIEE Protective Devices Committee as stated by the authors. However the minutes of that meeting do not bear out the authors' statement that: "The manufacturers stated that the crest value of discharge voltage for a 5,000 ampere 5,000-ampere-per-microsecond discharge current is approximately the same as the crest value of discharge voltage for a 10,000 ampere 10x20 discharge current."

The duration of the crest discharge voltage is dependent upon the total time that the current continues to rise at a given rate. The voltage peak on a 5,000-ampere test would have about one fourth the duration of the voltage peak on a 20,000-ampere test.

Another comparison can be made between the discharge voltage at a given crest current using a steep-front current wave and a slow-front current wave. Such a comparison is made in the three oscillograms shown in Figure 1 of this discussion. The left-hand oscillogram shows the lightning-arrester discharge voltage "V" and the 5,000 ampere 10x28 microsecond discharge current wave "I." The center oscillogram shows the characteristic of the same lightning arrester on a 5,000 ampere 3x23 microsecond current wave. The crest

Figure 1. Lightning-arrester discharge voltages on slow-front and steep-front 5,000-ampere surges

Left—10×28 microsecond current wave
Center—3×23 microsecond current wave
Right—Discharge voltages superimposed

voltage is higher. For direct comparison, the same tests were run again and the two voltages recorded on the film on the right. This shows that the lightning-arrester discharge voltage on the steep-front current wave may be higher in crest value but falls rapidly so that after 4 microseconds it is below the lightning-arrester discharge voltage on the slow-front wave. The authors give careful consideration to the strength of transformer insulation on chopped waves and on full waves with superimposed short time overvoltages, but ignore the fact that the lightning-arrester crest voltage on which they base their co-ordination system is only a short duration peak on a long tail wave.

To be good protectors, valve lightning-arrester discharge voltages of necessity fall in a fairly narrow band for a wide range of discharge currents. The effects due to current wave shape fall in this same band of voltages. A co-ordination system can better be based on the discharge voltage of the lightning arresters on a 10x20 microsecond current wave shape. Allowance for the effect of steep front waves can then be made in the margins, if it is found that the probability of occurrence of such rates of rise is sufficiently high.

C. F. Wagner (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The evaluation of the magnitude and the rate of rise of lightning-arrester discharge currents is fundamental to the whole problem of insulation co-ordination. Other discussions of these papers have attempted to evaluate these quantities by analyzing the available data pertaining to actual lightning-arrester discharge currents. The present discussion attempts to arrive at these values by analytical means using the available lightning stroke current data as a starting point.

The vast majority of transmission lines in this country operating at 115 kv and above have ground wires installed over them either for their entire length or for a distance about a mile from each substation.

A working group of the Institute under the chairmanship of Dr. E. R. Whitehead in a recent unpublished report outlined a method for determining the lightning performance of transmission lines. In this report it is assumed that the stroke currents having values in excess of 30 to 40 kiloamperes can be represented by a 4x40 wave, that is, a wave that rises to crest in 4 microseconds and decays to half value in 40 microseconds. Lightning in striking a tower raises the tower top voltage and if sufficiently great will cause flashover of the insulator string. From information obtained from E. L. Harder and J. M. Clayton, who made the analogue computer study for the above-mentioned report, the wave shape of the tower top voltage for a 1,000-foot span has the general form indicated by the upper curves shown in Figure 2 of this discussion. These curves for the present purpose can be regarded as typical of other span lengths also. Assuming a 30 per cent coupling factor, before flashover the conductor voltage is 0.3 of the tower top voltage and the voltage across the supporting insulator string is 0.7 of the tower top voltage. Depending upon the magnitude of the stroke current, flashover occurs at different times. The minimum voltage that still causes flashover occurs near 4 microseconds. Using as unit voltage the 1.5x40 insulation level of the line, Figure 2 of this discussion shows the relative values of various voltages concerned in this analysis for flashovers occurring if the flashover occurs at 2 or 4 microseconds.

Figure 3 of this discussion depicts the voltage and current waves on the ground wire and conductor for the 4-microsecond flashover. Prior to flashover the current wave in the conductor is zero and the voltage wave appears because of mutual coupling with the ground wire. After traveling one or two spans, that part of the current wave in the ground wire (and its associated voltage wave) disappears by drainage to ground. One can, therefore, neglect those portions of the voltage and current waves before the instant of flashover. At the instant of flashover the ground wire potential drops suddenly, the magnitude being dependent upon the relative values of conductor, tower, and footing impedances. For present purposes the reduction was taken as 10 per cent. At the same time the conductor rises to the same potential as the ground wire. These equal potentials are designated in Figure 3 as E.

After traveling one or two spans the voltage on the ground wire disappears but the current component in the phase conductor continues with unattenuated magnitude. The relative values of currents and voltages are shown for the position B in Figure 3.

The foregoing premised the flashover of a string of insulators at one tower only. Actually, when the tower-top voltage is sufficiently great to cause flashover at 2 microseconds, flashovers at adjacent towers are likely to occur. At the instant of flashover at the struck tower the ground wire and conductor voltages become equal. Equal voltage waves propagate along the ground wire and conductor. When the next tower is reached, however, the ground wire voltage drops suddenly and a difference in voltage builds up across the insulator string of sufficiently high value to cause flashover. This is the same phenomena depicted in Figure 3 which shows that the conductor voltage at the adjacent tower is reduced to 70 per cent of its value at the struck tower. If the voltage on the ground wire drops to substantially zero, the voltage across the string of insulators at the adjacent tower will be about 140 per cent of the insulation level of the line—sufficient to cause flashover of the insulators at adjacent towers. It would appear then that the conditions in Figure 2(A) for the flashover of one tower should be limiting. One would not expect voltages that are much greater than these to appear on the system.

If the lightning arrester is represented simply by a device having a drop E_a, independent of current, the lightning-arrester current at any instant can be determined by the expression given in Figure 3. If, further, a so-called 80 per cent lightning arrester (0.84xnominal system voltage) is assumed and since the voltage drop across the blocks is 3.67xlightning arrester voltage rating (at 5,000 amperes discharge current) then the lightning-arrester discharge current can be determined in terms of E and the system voltage by the expression also given in Figure 3.

Transmission lines for both 115 kv and 230 kv (to cover the range above 92 kv) are in existence having insulation levels that vary between 500 kv and 1,500 kv. Using the crest values of voltage E obtained from Figure 2, the maximum lightning arrester discharge currents shown in Table I of this discussion were obtained. While the values for a time to flashover of 4 microseconds are the important ones, the values for 2-microsecond flashover are also included. Corona and earth resistivity slope the wave front of incoming voltage surges considerably. The available data indicate that in one mile a square-front surge would be sloped so that its crest would be slowed to 2 microseconds in fair weather. Figure 2 gives an idea of the extent to which the wave front would be distorted and attenuated. The closer the strokes to the station, the higher the rate of rise of lightning-arrester discharge current. The eighth row of Table I, based upon a front retardation of 2 microseconds per mile, gives the distance in miles in which the stroke must occur to produce rates of rise of lightning-arrester discharge currents in excess of 5,000 amperes per microsecond. The great majority of strokes occur during a rain storm, for which condition corona and

Figure 2. Wave form of voltages at tower

Figure 3. Voltage and current waves on ground wire and conductor for 4-microsecond flashover

attenuation will be greater. The seventh row gives the time to attain the crest current or the approximate duration of the high rate of rise of current. Lightning arrester engineers state that the crest of the lightning-arrester drop is largely dependent upon the rate of rise of current. For a conventional 10x20 wave at which lightning arresters are usually tested, for a 5,000-ampere crest, the maximum rate of rise is approximately 1,000 amperes per microsecond. A 5,000-ampere-per-microsecond current wave produces a voltage drop that is 15 to 20 per cent higher. The discussion by Mr. Opsahl discusses this point in more detail.

The magnitude and rate of rise of the lightning-arrester discharge current is not the entire story. The frequency with which these currents can be obtained must be taken into consideration. From the lightning performance report, values of the ratio of tower-top voltages to stroke current were obtained for several values of tower footing resistance. From this number the stroke currents required to produce flashover were obtained. Then with the aid of the stroke-probability curve the probability of occurrence per 100 miles per year was obtained. The last two rows in Table I give the probability of occurrence per year per installation of a rate of rise of lightning arrester current exceeding 5,000 amperes per microsecond.

The first significant conclusion to draw from Table I is the desirability, because of its effect upon the probability factor, of holding the tower footing resistances to 20 ohms or lower for the first mile from the station. Considering only the 10- and 20-ohm footings, for the 1,500-kv levels the probability of occurrence of a 5,000-ampere per-microsecond discharge is extremely low. In the 500-kv levels, while the probability is somewhat higher, the duration of the high rate (row 7) is so short that it can have little effect upon transformer insulation.

There still remains the consideration of side flashes—strokes that strike the conductor directly instead of the ground wire On a well-laid-out ground wire system, this will represent about 0.1 of one per cent of the strokes or about 0.001 stroke per mile per year. High current side flashes flash the insulator string but there is a limiting value of current below which flashover will not occur. This current is very low and, using the same wave shape as the Lightning Performance Working Group, it will have a 2x40 wave shape. Using the same surge impedance as the working group (460 ohms) this limiting current will be 500x2/460 or 2,170 amperes for a line with an insulation level of 500 kv and 1,500x2/460 or 6,500 ampere for a 1,500-kv line. For the 500-kv level this limit represents 98 per cent of the strokes and for the 1,500-kv level about 80 per cent. These strokes perform essentially the same as strokes to the ground wire, perhaps a little less severe as they do not possess the sharp discontinuity illustrated in Figure 3(B). In any event they add a negligible amount to the probability of occurrence. The remaining side flashes produce a 2x40 wave that in the limit gives rise to a lightning-arrester discharge current of about 4,000 amperes in 2 microseconds for the 500-kv insulation level and to 12,000 amperes in 2 microseconds for the 1,500-kv level. Considering the probability of occurrence of a side flash within the first half mile (0.0005), the fact that 2 per cent of these for the 500-kv level and 20 per cent for the 1,500-kv level do not cause flashover and that only a portion of these produce currents as high as 12,000 amperes in 2 microseconds, the contribution of side flashes to the probability of occurrence of lightning-arrester discharges of the order of 5,000 amperes is negligible.

In conclusion it must be borne in mind that a great element of judgment is present in determining the basic assumptions to use in insulation co-ordination. Pyramiding the most severe conditions for all assumptions leads to ridiculous results. In selecting a lightning-arrester discharge current the probability of the simultaneous occurrence of the worst condition for other factors, such as location of protected device, length of down lead and tower footing resistance, must be considered. Bearing in mind these other fortuitous factors and the short duration of the higher lightning-arrester voltage associated with high rates of current rise, it appears that the probability of occurrence (about one per 200- to 500-lightning arrester locations per year) of rates of rise of currents of 5,000 amperes per microsecond is too infrequent to use as a basis of co-ordination. The lightning arrester characteristic corresponding to the conventional 10x20 wave is sufficiently representative.

E. Beck (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The paper follows the pattern of a memorandum pre-

Table I. Magnitude and Probability of Occurrence of Lightning Arrester Discharge Currents

Insulation Level of Line in Kilovolts	500						1,500					
Magnitude												
Time to flashover of insulator string, microseconds		4			2			4			2

Figure 4. Lightning currents through lightning arresters

sented by Mr. Clem for the National Electrical Manufacturers Association group, to the Edison Electric Institute and AIEE groups of the Triple Joint Committee on Insulation Co-ordination. It did not represent the opinion of all manufacturers, and the Lightning Arrester engineers of my company registered objection because we felt sufficient consideration had not been given to several items before conclusions were adopted. Thus we also find ourselves not in agreement with some of the steps discussed in the paper.

I would like to see a more detailed discussion of the method used to arrive at the curve of Figure 2 of the paper. I am cited twice in Figure 2 of the paper as a reference for the data. I wish it understood clearly that I am not a party to the curve of the authors' Figure 2. In my opinion it is not logical to lump all data on wave fronts in a curve regardless of corresponding crest currents and I am inclined to believe that this is what the authors have done. Nor does it appear to me logical to apply the data in the references cited, obtained on unshielded wood pole lines in highly exposed locations to the shielded lines considered in the paper.

A more significant way of presenting the data is shown in Figure 4 of this discussion prepared by Mr. Opsahl from the data obtained in our field investigations. It shows the number of discharges of recorded crest current and wave front per 100 lightning-arrester years. It is to be noted that there are 28 records with fronts of 1 microsecond but they are all less than 500 amperes, hence of no practical interest in co-ordination. What we are interested in is the probability of occurrence of high currents with short fronts. This is not frequent even on lines without shielding, and I wish to repeat that the data in Figure 4 of this discussion consist only of measurements on unshielded wood pole lines.

It has been found that the probability of short-front currents of appreciable magnitude on shielded lines is much less.

Therefore I am of the opinion that the 5,000-ampere-per-microsecond 5,000-ampere crest is not a realistic figure for 115-kv systems and higher, that are shielded as indicated in the paper. The use of this discharge current also colors the conclusions in the companion paper on the evaluation of lightning-arrester lead lengths by Carpenter Johnson and Saline,[1] cited in Table III of the authors' paper. These conclusions are too conservative.

In reference to taking advantage of a stacking factor in lightning arresters, we are of the opinion that this is not good practice because it has been found that the variations in characteristics are not purely random except over a long period of manufacture. If a stacking factor were used, why not base it on 3-kv elements instead of 12 kv, giving a still greater advantage? Why was 12 kv selected by the authors? As far as I know, 12-kv units are not a standard of the industry, for either station- or line-type lightning arresters.

I concur with the authors' comments on the necessity of keeping in mind considerations of wet 60-cycle flashover and creepage.

Reference

1. See reference 11 of the paper.

W. J. Rudge: None of the discussions of our paper indicate any disagreement with the values of basic impulse insulation levels proposed in our paper. This is very gratifying. Apparently there is a misunderstanding in reference to the discharge voltage of a 12-kv lightning arrester rating for a 5,000-ampere crest 5,000-ampere-per-microsecond, current discharge wave. In our paper we said "the manufacturers stated" that this discharge voltage was the same as for a 10,000-ampere 10x20-microsecond current wave. We made this statement in good faith because our notes taken at the meeting in question indicate that the statements were made.

Most of the discussions questioned our choice of the lightning-arrester discharge current upon which we based our study. We knew that a rate of current rise of 5,000 amperes per microsecond will occur very seldom, and in going over the available field data we noted that the higher rates of current rise were frequently associated with relatively low crest values of discharge current. We chose the current wave shape after careful consideration with full understanding that it was conservative.

In view of the fact that there was very little data available we felt, and still feel, that we were justified in being conservative. If further statistical data becomes available indicating that a slower rate of rise is preferable, we will be agreeable to using that which can be justified.

The oscillograms submitted by Mr. Opsahl (Figure 1 of the discussion) confirm our preference for a wave faster than the 10x20 microsecond wave. In the oscillogram giving the 3x23 current wave it is noted that the voltage wave is close to a 1x20 wave. The current wave we used is about a 2x20 wave and gives about a 0.5x30 voltage wave. Both of these are much closer to the standard 1.5x40 voltage wave upon which impulse tests are based than is the voltage wave given by the 10x20 current wave.

Mr. Wagner has presented a theoretical discussion outlining a method of estimating the number of occurrences of a rate of rise exceeding 5,000 amperes per microsecond. He gets figures ranging from zero to one in 0.7 of a year. We prefer to use the results of actual measurements obtained in the field even though the data may not be as complete as we would like to have it.

Mr. Beck implies that we used the stacking factor in arriving at the proposed impulse insulation levels. We did not use it to determine the BIL's but merely put it in for information and to indicate what might be done if full credence was given to it.

Co-ordination of Lightning Arrester Location with Transformer Insulation Level

R. L. WITZKE
MEMBER AIEE

T. J. BLISS
ASSOCIATE AIEE

THE location of lightning arresters, relative to the equipment being protected, must be given careful consideration if adequate protection is to be provided at reasonable cost. This is particularly true if equipment having reduced insulation levels is used for economy reasons. Unfortunately, a large number of factors must be considered in determining the number and location of lightning arresters in most substations. The more important factors include the number, insulation level and shielding of lines entering the station; substation shielding; length of individual bus sections; distances between bus and equipment; capacitance of circuit breakers, transformers and other equipment; lightning arrester lead lengths; equipment insulation levels; and magnitude and rate-of-rise of surges entering the station. All of these factors, as well as others, must be considered in any complete evaluation of economical substation protection. The authors are of the opinion that each case must be studied individually if adequate protection is to be provided at a minimum cost. Individual studies of large, high-voltage substations on an analogue computer, or by other means, are certainly justified. In the case of the smaller or lower voltage stations, extensive studies cannot be justified, and protection must be based on established rules, which of necessity must be quite conservative.

In view of the complicated nature of the substation protection problem, the authors have limited the scope of their investigation to the relatively simple case of a single overhead line terminated in a single transformer bank. The results of this study, as summarized in this paper, will be conservative when applied to stations having a multiplicity of circuits. Several special studies were made to show the influence of additional circuits on the transformer protection provided. All studies reported were made on the Anacom, or analogue computer.[1]

Summary and Conclusions

The general studies reported in this paper are limited to the surge protection of a liquid-filled power transformer located at the end of a transmission line as shown in Figure 1. The results are expressed in terms of the distance s, the maximum permissible distance between the transformer bushing and the lightning arrester lead tap to the bus, point a, in Figure 1. The summary tables included in this section are based on 35 feet of lead between the lightning arrester and the bus; however, the general computer data may be used to evaluate protection with other lightning arrester lead lengths.

It has been concluded that protection based on an incoming surge having a maximum rate-of-rise of 500 kv per microsecond is adequate, if the station is provided with shielding against direct strokes[2] and the overhead line is provided with properly located ground wires,[3,4] for at least one-half to one mile out from the station. Under these conditions, it appears reasonable to assume that the lightning arrester current is limited in magnitude by the line insulation level and surge impedance. Based on a line surge impedance of 450 ohms, which is typical for lines with overhead ground wires, and an incoming surge having a maximum rate-of-rise of 500 kv per microsecond, the rate-of-rise of the lightning arrester current will not exceed 2,220 amperes per microsecond.

With the maximum rate-of-rise of the lightning arrester current limited to approximately 2,220 amperes per microsecond, satisfactory co-ordination is obtained by using the maximum 10×20 lightning arrester discharge characteristics and the transformer chopped-wave level, in determining the permissible distance between a lightning arrester and a transformer. It should be noted that the voltage at the transformer may exceed the chopped-wave level if the rate-of-rise of lightning arrester current is as high as 2,220 amperes per microsecond and the lightning arrester has maximum discharge characteristics. However, due to the wave shape of the surge voltage applied to the transformer, the impulse level of the transformer is not exceeded. This conclusion gives due consideration to the duration, as well as the magnitude, of the voltage at the transformer.

It has been concluded that station ground resistance is a negligible factor, at least in the general case. Most stations will be provided with a ground mat having a low resistance to ground. In all cases, good engineering practice will dictate connecting lightning arresters and all apparatus tanks to a common ground in order to equalize potentials within the station for safety reasons. With the lightning arrester ground and the transformer tank interconnected by a counterpoise system, all of the resistance between the counterpoise and ground will not be effective in increasing the voltage across the transformer. The transformer tank will rise above ground potential,

which partially offsets the increase in voltage produced by the lightning arrester current discharging into the resistance between the ground mat and ground. If the lightning arrester has a separate ground of appreciable resistance, the voltage across this resistance must be considered in surge-protection problems.

Application Guides

The application guides included in this section are limited to the surge protection of power transformers located at the end of a transmission line as shown in Figure 1. The guides are in the form of tables giving suggested maximum distances between the transformer bushing and the lightning arrester lead tap to the bus (distance s in Figure 1). The limiting distances are based on the following assumptions:

1. Any surge reaching the station has a maximum rate-of-rise of 500 kv per microsecond. This requires that the station be provided with adequate shielding against direct strokes,[3] and the overhead line be provided with properly located ground wires[5,6] for at least one-half to one mile out from the station.

2. Lightning arrester current is limited by the line insulation level and line surge impedance.

3. The overhead-line insulation levels do not exceed the values in Table I.

4. Lead between lightning arrester and bus does not exceed 35 feet.

5. The transformers have full insulation unless otherwise specified.

6. Station ground resistance is neglected.

In using these tables it is necessary to know the transformer basic impulse insulation (BIL) and the type and rating of the lightning arrester. The lightning arrester rating is, of course, determined by the system voltage and grounding conditions. The maximum distances given in the tables are measured between the transformer bushing and the lightning arrester tap to the line or bus. If the suggested distance is exceeded in a particular case, special study is required. General data are included in later sections for more detailed investigations where these are necessary.

The data in Table II are based on transformers having full insulation and standard 80 or 100 per cent lightning arresters. The data in Table III are based on transformers with reduced insulation and special lightning arrester ratings. The lightning arrester ratings were obtained by taking 80 per cent or 75 per cent of 1.05 times system voltage to obtain a minimum lightning arrester rating. The added restriction that the ratings be a multiple of three increases most of the

Figure 1 (left). Circuit studied in general investigation

C = equivalent capacitance of transformer
S_2, V_2, C_2 = lightning arrester analogue

ratings above the calculated minimum values. These ratings should not be applied without giving careful consideration to the dynamic voltage across the lightning arrester during fault or unusual system conditions.

The effect of varying the rate-of-rise of the incoming surge and the lightning arrester lead length is indicated by the results in Table IV.

The influence of a second line entering the station is indicated by the data in Table V. These results apply for the case of a 200-foot separation between the arrester and the transformer (distance s in Figure 1), an overhead line surge impedance of 500 ohms, and a front F of 0.8 microsecond, neglecting the second line. The second line was terminated at the lightning arrester, at the transformer and at 50-foot intervals between these limits. The results are given in terms of the voltage at the transformer, expressed as a ratio to the voltage at the lightning arrester. The equivalent surge capacitance was varied between zero and 0.0032 microfarad. It will be noted that the second line has considerable influence on the voltage ratios, particularly if the termination is close to the transformer. This illustrates the need for considering all factors in any complete study of substation protection.

Basis of General Investigation

The general study reported in this paper was limited to the case of a single overhead transmission line terminated at a transformer bank as illustrated in Figure 1. It is assumed that the station is adequately protected against direct strokes, and the transmission line is provided with properly located ground wires, for at least one-half to one mile out from the station. It is assumed that any surge reaching the lightning arrester originates out on the line and that the lightning arrester current is limited by the line surge impedance. The station bus is treated as an extension of the line and no distinction is made between horizontal and vertical runs. The distance s, between the lightning arrester location and the transformer, is taken as the total distance between the lightning arrester lead tap to the bus and the transformer bushing. In these studies the transformer is represented by an equivalent surge capacitance C, which is permissible for surges of short duration.

The studies were based on an incoming surge voltage e having a uniform rate-of-rise de/dt. Unit voltage, or 100 per cent voltage, is defined as the maximum surge voltage at the lightning arrester location. The voltage at the lightning arrester location is assumed to rise to this unit voltage and then to remain constant at least until the maximum voltage at the transformer is reached.

Unit time, referred to in this paper as F, is defined as the maximum surge voltage at the lightning arrester location divided by the rate-of-rise of the incoming surge. If the distance between the lightning arrester and the transformer were unusually long, the voltage at the lightning arrester would reach its maximum voltage before reflections returned from the transformer. In this case, and based on the assumptions made, the voltage at the lightning arrester location would follow the solid line in Figure 2, and F would be the time to maximum voltage. In the more practical cases, negative reflections will return from the transformer before the voltage at the lightning arrester location reaches its maximum value. The voltage at the lightning arrester is then modified as indicated by the dashed line in Figure 2, and the time to maximum voltage is increased. These reflections, however, do not influence the basic definition of unit time F. These definitions of unit voltage

Figure 2. Voltage at lightning arrester location as assumed in general studies

and unit time were selected to permit generalization of the data obtained in the analogue computer studies.

Let

v = velocity of surge propagation in feet per microsecond.
Z = line or bus surge impedance in ohms.
F = maximum voltage at the lightning arrester location divided by the rate-of-rise of the incoming surge.

Then

s/v = time required for surge to travel from lightning arrester location to transformer.
ZC = time constant in microseconds of the circuit consisting of the bus and the terminating capacitance.

The times F, s/v, and ZC are the only variables that need be considered in the problem. Dividing s/v and ZC by F reduces the problem to two fundamental variables $(s/v)/F$ and ZC/F.

Analogue Computer Studies

The analogue computer studies were made using the analogue in Figure 3. The overhead line between the lightning arrester location and the transformer was represented by pi-sections, and the transformer by a capacitor C.

The transmission line entering the station was represented by the resistor R_2 having a resistance equal to the line surge impedance. It was assumed that the overhead line and bus surge impedances were equal. Capacitor C_1 was charged through resistor R_1 by closing switch S_1. The voltage across C_1, which had a uniform rate-of-rise, was applied to the station bus through the transmission line surge impedance R_2. The voltage at point (a) was allowed to increase until it was equal to the battery voltage V_2, at which time switch S_2 was closed to hold the voltage constant at this point.

The voltages at the lightning arrester location (a) and across the transformer represented by C, were measured with a cathode-ray oscilloscope. The circuit lengths and terminating capacitance

values used in the studies were selected to cover a range of $(s/v)/F$ and ZC/F ratios expected in practice.

General Data

Typical oscillograms obtained in the Anacom studies are included in Figures 4 and 5. The upper line of oscillograms in each figure shows the voltages that would be obtained at the lightning arrestor location with no reflections from the transformer. These records were obtained by replacing the capacitor C by a resistance equal to the line surge impedance. One per unit time F is defined as the time to the maximum voltage on these records. The second line of oscillograms in Figure 4 shows the voltage at the lightning arrester location with zero terminating capacitance, that is, with an open-end line. The successive lines illustrate the voltages at the lightning arrester location with ZC/F ratios up to 2.0.

The second line of records in Figure 5 is the voltage at the end of an open-wire circuit. The succeeding lines illustrate the voltages at the transformer with ZC/F ratios up to 2.0. It should be noted that attenuation was neglected in obtaining these results. Practical attenuation values will have little influence on the magnitude of the first crest, but will reduce the second and successive crests appreciably.

Figure 6 summarizes the maximum receiving-end voltages (voltages at transformer) as obtained in the computer studies. These voltages are expressed as a ratio to the maximum voltage at the lightning arrester location. Table VI is a summary of the E_r/E_s and T/F ratios obtained. In this table, T is the time to maximum voltage at the transformer.

Table IV. Influence of Lightning Arrester Lead Length and Rate-of-Rise of Incoming Surge on Maximum Distance Transformer to Lightning Arrester Lead Tap

System Voltage, Kv	Line Insulation Level, Kv	Rate-of-Rise of Incoming Surge, Kv Per Microsecond	Maximum Distance, Feet — Lead Length 0 Feet	35 Feet

		500	176	126
		1,000	88	45
230	1,440	250	460	417
		500	230	187
		1,000	115	65

Note: Above distances are based on the following: full transformer insulation; and standard 90 per cent station-type lightning arresters.

Integration Method

In surge protection problems involving appreciable lead length between the protective device and the protected equipment, consideration must be given to the wave shape, as well as the magnitude, of the surge voltage applied to the equipment. Apparatus insulation levels are expressed in terms of test waves having definite shapes. If the wave shape of the surge applied to equipment deviates from these test wave shapes, considerable judgment must be exercised in estimating the permissible magnitude of the surge. The industry is in need of an acceptable method of evaluating the influence of surge voltages of nonstandard wave shape on electric apparatus. Any method finally adopted should be substantiated by laboratory test results.

In the paper Surge Protection of Cable-Connected Equipment,[8] the authors proposed an integration method of evaluating the effect of surge voltages of nonstandard wave shape on oil-insulated transformers. In this method the disruptive effect of the surge is defined by the equation

$$DE = \int [(e(t) - K_1)]^{K_2} dt \qquad (1)$$

where

DE = disruptive effect
$e(t)$ = surge voltage expressed as a function of time
K_1, K_2 = constants fixed by transformer test voltages

This relation was established on the basis that the transformer insulation could stand some constant voltage K_1 for an extended period of time without distress. It was realized that the disruptive effect of a surge is a function of both voltage magnitude and time, but that these two factors should not be given equal weight. The constant K_2 was introduced to allow some variation in the relative weight given to magnitude and time. The constants K_1 and K_2 can be evaluated from the standard impulse tests for transformers if the assumption is made that the full-wave, chopped-wave, and front-of-wave tests are of equal severity. The constants are obtained by solving the following relations

$$\int [(e_1(t) - K_1)]^{K_2} dt = \int [(e_2(t) - K_1)]^{K_2} dt \qquad (2)$$

$$\int [(e_2(t) - K_1)]^{K_2} dt = \int [(e_3(t) - K_1)]^{K_2} dt \qquad (3)$$

In these equations $e_1(t)$, $e_2(t)$, and $e_3(t)$ are the full-wave, chopped-wave, and front-of-wave test voltages, respectively, expressed as a function of time. The general form of the equations is such that a cut-and-try solution is required. After K_1 and K_2 have been determined, the disruptive effect of a standard test wave is determined by substituting one of the standard test waves in equation 1. All three test waves should give the same DE when used in equation 1.

As the equation gives the same disruptive effect for the three standard test waves, which vary over a wide range in magnitude and duration, it should give acceptable accuracy in evaluating the nonstandard wave shapes normally encountered in surge-protection applications. Judgment, however, must be used in evaluating oscillatory waves as experienced in cases involving appreciable lead length between the lightning arrester and the transformer. The authors have integrated only the first cycle of these oscillations because the second cycle is of appreciably reduced magnitude, and because the stresses in the transformer insulation are relieved to some extent during the period of low voltage between the first and second crests of the oscillation.

The authors evaluated K_1, K_2, and DE for insulation classes between 5.0 and 34.5 kv, and included them in Table XIII of the paper referred to previously. Since then it has been discovered that the integration method, based on equation 1, has a limitation when used at the higher circuit voltages because no combination of the constants K_1 and K_2 will give the same DE for all three test waves. In order to retain the method, at least until a better approach to the problem is developed, an approximation had to be introduced. This consisted of setting K_1 equal to zero and then finding K_2 by solving equation 2, which is based on the full-wave and chopped-wave transformer tests. This procedure gave results for 138-kv class insulation as follows:

$K_1 = 0$
$K_2 = 10.3$
$DE = 660 \times 10^{10}$

These constants give the same DE for the full-wave and chopped-wave test volt-

Table V. Influence of Second Line Entering Station

Location of Second Line Termination in Feet from Arrester	E_r/E_s — Capacitance C in Microfarads 0	0.0008	0.0032
0	1.2	1.39	1.66

No second line	1.43	1.60	1.70

Note: Above data based on 200 feet between lightning arrester and transformer, overhead line surge impedance of 500 ohms and a front F of 0.8 microsecond, neglecting the second line.

Figure 4. Typical voltages at lightning arrester location as obtained on Anacom

Figure 5. Typical oscillograms showing voltages at transformer

ages, and a second value for the front-of-wave test voltage. The integration method, based on these constants, will permit a front-of-wave test voltage approximately 5 per cent higher than the standard test for 138-kv class insulation. This error, however, was of little practical importance in the cases included in this paper because the surge voltages permitted had magnitudes much closer to the chopped-wave than the front-of-wave levels.

The integration method permits expressing a surge voltage of nonstandard wave shape in terms of an equivalent chopped-wave or full-wave voltage. For example, the voltage in Figure 7 consists of a combination of the chopped-wave and full-wave test voltages for 138-kv class transformers. The voltage rises to 750 kv in $1^1/_2$ microseconds, decreases to 650 kv at 3.0 microseconds and then follows the tail of a $1^1/_2$x40 wave. The *DE* of this voltage is $1{,}183 \times 10^{33}$, which is the same as the *DE* of a 689 kv $1^1/_2$x40 voltage wave. It is concluded that this voltage is approximately equivalent to a $1^1/_2$x40 voltage, 6 per cent higher than the 650-kv full-wave test voltage.

Insulation Co-ordination

As discussed in the previous section, consideration should be given to the wave shape of surge voltages applied to transformers. In co-ordinating lightning arrester characteristics with transformer insulation levels, consideration also should be given to the rate-of-rise of current in the lightning arrester because this influences the magnitude and wave shape of the lightning arrester discharge voltage. The authors, however, have concluded that satisfactory results can be obtained if the 10x20 lightning arrester discharge characteristics are co-ordinated with the chopped-wave level of the transformer. This conclusion is limited to those cases involving appreciable lead between the lightning arrester and the transformer. It also assumes that the maximum rate-of-rise of current in the lightning arrester does not exceed approximately 2,220 amperes per microsecond.

The basis for this conclusion is discussed in connection with the following example: The maximum permissible distance between a 138-kv class transformer and the lightning arrester location (distance *s* in Figure 1) is 132 feet, assuming a 121-kv lightning arrester and 35 feet of lead between the lightning arrester and the bus. This distance was calculated by using the 10x20 lightning arrester characteristics and co-ordinating with the transformer chopped-wave level of 750 kv. Under the assumed conditions, as outlined in the detailed example in a later section on the application of the computer data, the lightning arrester current is 3,580 amperes and the rate-of-rise of lightning arrester current is 2,220 amperes per microsecond. The latter value assumes a 500-kv per microsecond surge reaching the station over a 450-ohm line. The lightning arrester discharge voltage used in obtaining the permissible distance of 132 feet was 429 kv, which was based on a 3,580-ampere, 10x20 discharge current.

An 8,900-ampere, 10x20 discharge current has a rate-of-rise of approximately 2,220 amperes per microsecond. The maximum voltage across a 121-kv lightning arrester at this current is 473 kv, which is 10 per cent higher than used in the above example. Increasing the arrester voltage to this value, and leaving

Note: Upper value is E_r/E_s ratio, and lower value (in parenthesis) is T/F ratio.

the distance between the transformer and the arrester location equal to 132 feet, increases the voltage at the transformer to 807 kv, which is 7.5 per cent above the transformer chopped-wave level. The general shape of the transformer voltage is illustrated by the oscillogram in Figure 5 for an $(s/v)/F$ ratio of 0.125 and a ZC/F ratio of 1.0. The time to maximum voltage is approximately 2.30 microseconds based on the data in Table VI. This voltage, with a crest of 807 kv, is equivalent to a chopped-wave test voltage of only 744 kv. This equivalence gives due consideration to the duration as well as the magnitude of the voltage applied to the transformer, and was obtained by means of the integration method discussed in the previous section.

It is concluded that it is permissible to use the published 10x20 lightning arrester characteristics and the transformer chopped-wave level in determining the permissible distances between lightning arresters and transformers. This conclusion assumes that the maximum rate-of-rise of current in the lightning arrester does not exceed approximately 2,220 amperes per microsecond, which appears to be a reasonable upper limit if the station and incoming lines are adequately shielded.

Incoming Surge Voltage

In this investigation it is assumed that the maximum surge voltage reaching the lightning arrester is limited by the insulation level of the transmission line. In all cases considered, the crest voltage at the transformer is reached in less than 3.0 microseconds. To obtain the maximum voltage at the transformer, it is necessary to maintain the voltage at the lightning arrester location until crest transformer voltage is reached, or for times approaching 3.0 microseconds. For this reason it was decided to base the magnitude of the incoming surge on a line insulation level approximately equal to the 3.0-microsecond flashover value. However, the line full-wave level is usually known, a line level 20 per cent above the full-wave level was used. This is very close to the 3.0-microsecond flashover value of wood-pole and steel-tower lines as normally designed and built.

The rate-of-rise of the incoming surge is of considerable importance in evaluating the influence of lightning arrester location on the protection afforded. For this reason, some conclusion must be reached regarding the front of the incoming surge. Brune and Eaton,[6] in field tests with artificial surges, showed that the time to crest voltage of an 850-kv surge increased from 2.0 microseconds at the point of surge application to 5.0 microseconds after traveling 1.4 miles. The maximum rate-of-rise of voltage decreased from approximately 1,000 kv per microsecond to 133 kv per microsecond in the same distance. Rorden[7] applied an 800-kv surge, having a front of less than $^1/_2$ microsecond, to a 1-mile open-wire circuit, and measured a time to maximum voltage of approximately 2.0 microseconds at the open end. The results of these tests and of analytical calculations[8] show that corona has considerable influence in sloping surge voltages high enough to be of importance in station-protection problems. However, insufficient statistical data are available to prepare a satisfactory probability curve on the fronts of surges reaching stations. The authors have based their suggested protection, as given in the tables in the application guides, on a rate-of-rise of 500 kv per microsecond. This appears to be a reasonable upper limit for surges originating at some distance from the station. However, the general data included in this paper permits a consideration of other rates-of-rise.

Surge Voltage at Lightning Arrester Location

The surge voltage at the lightning arrester location is a function of the following factors:

1. Lightning arrester discharge voltage (IR drop).
2. Lightning arrester lead drop.
3. System dynamic voltage.
4. Station ground resistance.

Each of these items, as well as factors affecting them, will be discussed in this section.

Figure 6. Maximum voltage at transformer expressed as a ratio to the maximum voltage at the lightning arrester location

Figure 7. Combination of chopped-wave and full-wave test voltages for a 138-kv class transformer

Lightning Arrester Voltage

The current in a lightning arrester located at the end of a line is usually calculated using the following relation:

$$I=\frac{2e-e_a}{Z}$$

where

I = maximum lightning arrester current
e = crest value of incoming surge voltage
e_a = lightning arrester voltage

This equation has the limitation of requiring the lightning arrester voltage, which depends on the lightning arrester current, before finding the current. In order to eliminate the need for a cut-and-try solution, the authors have used an equation based on a lightning arrester analogue consisting of a d-c voltage and a resistance. The lightning arrester is assumed to have volt-ampere characteristics as illustrated in Figure 8. The lightning arrester resistance R is taken as the change in discharge voltage between 3,000 and 5,000 amperes divided by the change in current. The direct voltage E_0 is the lightning arrester voltage at zero current, based on a straight-line volt-ampere characteristic. The 3,000–5,000 ampere limits were used as being within range of the values encountered in the cases considered.

The lightning arrester current is then calculated as follows:

$$I=\frac{2e-E_0}{Z+R}$$

where

E_0 = lightning arrester voltage at zero current based on lightning arrester characteristics shown in Figure 8
R = lightning arrester resistance based on lightning arrester characteristics shown in Figure 8

The maximum lightning arrester voltage is then equal to E_0 plus IR.

The lightning arrester constants E_0 and R are given in Table VII for line and station lightning arresters between 30 and 242 kv. These values are based on average lightning arrester discharge voltages plus 10 per cent for station lightning arresters and plus 15 per cent for line lightning arresters. These maximum tolerances have been agreed upon by the members of the Lightning Protective Devices Committee of the National Electrical Manufacturers Association, and should eventually replace the present maximum tolerances of 15 per cent for station lightning arresters and 20 per cent for line lightning arresters.

Lead Drop

The voltage drop in the lightning arrester lead depends on the lead inductance and the rate-of-change of lightning arrester current. A lead inductance of 0.4 microhenry per foot is assumed in this paper as being typical. Lead lengths of 35 feet are used in the illustrative cases included; however, other lengths can be used with the data included.

The lead voltage is determined as follows:

$$L\frac{di}{dt}=\frac{2Lde/dt}{Z}$$

where

$\frac{di}{dt}$ = rate-of-rise of current in kiloamperes per microsecond

$\frac{de}{dt}$ = rate-of-rise of incoming surge in kilovolts per microsecond

L = lead inductance in microhenrys

In practical cases the circuit between the lightning arrester and the transformer, as well as the transformer capacitance, will modify the lightning arrester current. This factor was considered of secondary importance and is neglected in order to simplify application procedures. The lightning arrester current as calculated should be slightly conservative.

Table VII. Lightning Arrester Constants Based on Characteristics in Figure 8

Lightning Arrester Rating, Kv	Station Lightning Arrester E_0	Station Lightning Arrester R	Line Lightning Arrester E_0	Line Lightning Arrester R

Figure 8. Lightning arrester characteristics assumed in calculating lightning arrester current

Dynamic Voltage

In applications involving appreciable lead length between the lightning arrester location and the transformer, consideration should be given to the system dynamic voltage. If the dynamic voltage is of a polarity opposite to the polarity of the incoming surge, the change in voltage at the lightning arrester location is the sum of the lightning arrester voltage, lead voltage and the dynamic voltage. This change in voltage at the lightning arrester location increases the maximum voltage at the transformer over what it would be if dynamic voltage were neglected. This factor can be taken into account in using the computer data in Figure 6, if E_s is defined as the maximum change in voltage at the lightning arrester location. In this case E_s is obtained by adding normal line-to-ground crest voltage to the lightning arrester plus lead voltages.

If system dynamic voltage is included in E_s, then E_r, as used in Figure 6, is the maximum change in voltage at the transformer, and not the maximum voltage to ground. The maximum voltage change permitted at the transformer terminals depends on the magnitude and polarity of the system dynamic voltage at the time a surge reaches the transformer. In all cases the total voltage between the line terminals and ground must not exceed the transformer impulse level. If the dynamic voltage is equal to zero, the surge voltage applied should not exceed the transformer impulse level. However, if the dynamic voltage is equal to line-to-ground crest voltage, and of a polarity opposite to the surge polarity, E_r can be as high as the transformer impulse level plus line-to-ground crest voltage, without producing a total voltage to ground at the transformer terminals higher than the transformer impulse level. In using the data in Figure 6, normal line-to-ground crest voltage is added to the transformer impulse level in obtaining E_r. If dynamic voltage is included in E_r, it must be included in E_s.

Table VIII. Influence of Counterpoise on Transformer Voltage

F, Micro-Seconds	C, Micro-farads	E_r/E_s Counter-poise Neglected	E_r/E_s Counter-poise Included
0.8	0	1.46	1.46
	0.0008	1.63	1.68
	0.0032	1.72	1.80
1.2	0	1.28	1.28
	0.0012	1.46	1.50
	0.0048	1.54	1.60

Station Ground Resistance

Station ground resistance should be a negligible factor, at least in the general case. The larger stations will be provided with an extensive ground mat having a low resistance to ground. In all cases, good engineering practice will dictate connecting lightning arresters and all apparatus tanks or housings to a common ground in order to equalize ground potentials within the station for safety reasons. If the lightning arrester ground and the transformer case are interconnected by means of a counterpoise, all of the resistance between the counterpoise and ground is not effective in increasing the voltage across the transformer insulation. The transformer tank will rise above ground potential, which partially offsets the increase in voltage produced by the lightning arrester current discharging into the resistance between the counterpoise and ground.

A special computer study was made to show the influence of a counterpoise on the voltages across a transformer. In the case considered, 200 feet of lead was assumed between the lightning arrester location and the transformer. The ground end of the lightning arrester was connected to the transformer tank with a single buried conductor 200 feet long, having a surge impedance of 167 ohms and a leakage resistance to ground of 10 ohms. Several values of F and C were considered. The results in Table VIII give the voltages at the transformer, expressed as a ratio to the voltages at the lightning arrester location, with and without the counterpoise. In the latter case, without the counterpoise, station ground resistance was neglected entirely. The data in Table VIII shows that the counterpoise system does not increase the voltage at the transformer more than 5 per cent above the voltages obtained with a perfect station ground. In more practical cases, involving shorter distances between the lightning arrester and the transformer, and lower counterpoise-system surge impedance and leakage-resistance values, the effects will be even less than indicated by the data given in Table VIII.

If the lightning arrester has a separate ground of appreciable resistance, the voltage across this resistance should be added to the lightning arrester and lead voltages in obtaining the maximum voltage at the lightning arrester location.

Total Voltage Change at Lightning Arrester Location

The total voltage change E_s at the lightning arrester location is equal to the sum of the lightning arrester discharge voltage, lead voltage, and system dynamic voltage. This assumes that the lightning arrester ground resistance is negligible. Figure 9 illustrates the addition of the voltages included in E_s. The front F is obtained by dividing E_s by the rate-of-rise of the incoming surge voltage de/dt.

Circuit Constants

The circuit constants used in connection with Figure 6 are the overhead circuit surge impedance Z and the equivalent surge capacitance C of the transformer. If these constants are known, they can be used directly in the ZC/F ratio. A surge impedance of 450 ohms is used in calculations made in this paper, this value being typical for circuits with ground wires.

The surge capacitance of a transformer is considerably lower than the total capacitance of the winding to ground, and depends on the transformer design. In the absence of data on this capacitance, it is satisfactory to use the upper curve in Figure 6, this curve defining the maximum E_r/E_s ratio that can be obtained irrespective of capacitance. Considering practical ZC/F ratios, the use of this curve will introduce a maximum of 5 per cent error, and eliminates the need for knowing the capacitance in specific applications.

Application of Computer Data

In this discussion of the application of the computer data in Figure 6, the following symbols are used:

e = crest value of surge voltage entering the station

$\frac{de}{dt}$ = rate-of-rise of incoming surge in kilovolts per microsecond

Z = line surge impedance

E_a = lightning arrester voltage at zero current based on lightning arrester characteristics shown in Figure 8

R = lightning arrester resistance based on lightning arrester characteristics shown in Figure 8

$\frac{di}{dt}$ = maximum rate-of-rise of lightning arrester current in kiloamperes per microsecond

I = maximum lightning arrester current in kiloamperes

$L\frac{di}{dt}$ = lightning arrester lead voltage in kilovolts

E_4 = line-to-neutral crest system voltage in kilovolts

E_s = maximum voltage change at lightning arrester location

E_r = maximum voltage change at transformer

$F = \frac{E_s}{de/dt}$

E_s and E_r are obtained as follows:

$E_r = E_4 +$ transformer chopped-wave test voltage.

$$E_s = E_a + IR + L\frac{di}{dt} + E_4$$

where

$$I = \frac{2e - E_4}{Z + R}$$

$L = 0.4 \times$ lightning arrester lead length in feet

$$\frac{di}{dt} = \frac{2de/dt}{Z}$$

In using the computer data, E_r/E_s is first obtained and then $(s/v)/F$ is taken from Figure 6. In the absence of specific data on the transformer capacitance C, the upper curve in Figure 6 should be used. The permissible circuit distance s, between the lightning arrester tap and the transformer, is then obtained by multiplying $(s/v)/F$ by 1,000 F.

The following example will illustrate the procedure:

A 138-kv steel tower line with nine insulators enters a station protected with 121-kv station-type lightning arresters. The lightning arresters are connected to the bus through 35 feet of lead. Determine the maximum distance that should be permitted between the lightning arrester lead tap to the bus and the bushings of a 138-kv class transformer having a 750-kv chopped-wave level.

e = 1,020 kv (1.2 × full-wave impulse level of nine insulators)

Figure 9. Total change in voltage at lightning arrester location neglecting reflections from transformer

$\frac{de}{dt} = 500$ kv per microsecond (assumed)

$Z = 450$ ohms

$E_s = 391$ kv (from Table VII)

$R = 10.5$ ohms (from Table VII)

$L = 0.4 \times 35 = 14$ microhenrys

$$Ed = \frac{\sqrt{2}}{\sqrt{3}} 138 = 113 \text{ kv}$$

$$\frac{di}{dt} = \frac{2 \times 500}{450} = 2.22 \text{ kiloamperes per microsecond}$$

$$I = \frac{2 \times 1{,}020 - 391}{450 + 10.5} = 3.58 \text{ kiloamperes}$$

$IR = 3.58 \times 10.5 = 37.5$ kv

$$L\frac{di}{dt} = 14 \times 2.22 = 31.1 \text{ kv}$$

$E_s = 391 + 37.5 + 31.1 + 113 = 572.6$ kv

$E_r = 113 + 750 = 863$ kv

$E_r/E_s = 1.51$

From Figure 6, $(s/v)/F = 0.115$

$$F = \frac{573}{500} = 1.15 \text{ microseconds}$$

$s = 1{,}000 \times 1.15 \times 0.115 = 132$ feet

This length of circuit will limit the maximum voltage at the transformer to 750 kv.

Influence of Additional Lines

The data presented in Table V showed that a second line entering the station has considerable influence on the voltage at the transformer, and consequently on the permissible distance between the lightning arrester and the transformer. This section discusses a method of estimating the influence of one or more additional lines terminated at the lightning arrester or at the transformer. In this method the circuit between the lightning arrester and the transformer, and the transformer capacitance, is treated as a simple inductance-capacitance circuit.

If the additional lines are terminated at the transformer, the surge impedance of these lines is treated as a resistor in parallel with the transformer capacitance. The attenuation introduced by this equivalent resistance decreases the maximum voltage at the transformer. The ratio of transformer voltage to lightning arrester voltage is calculated as follows:

$$E_r'/E_s' = 1 + \epsilon^{-T/2Z'C}\left(\frac{E_r}{E_s} - 1\right)$$

where

E_r/E_s = voltage ratio as given in Figure 6, which neglects additional lines

Z' = equivalent surge impedance of additional lines in parallel

T = time to maximum transformer voltage neglecting additional lines

Values of T are given in Table VI, expressed as a ratio to the front F. These values must be multiplied by F to obtain the time to maximum voltage in microseconds.

In these calculations, conservative results will be obtained if a capacitance of 0.0032 microfarad is assumed in the absence of specific data. Smaller capacitance values will result in lower voltage ratios.

As an example, consider the following case: 200 feet between lightning arrester and transformer; overhead line surge impedance of 500 ohms; transformer capacitance of 0.0032 microfarad; front F of 0.8 microsecond. One additional line terminated at transformer.

Then

$$\frac{s/v}{F} = \frac{200/1{,}000}{0.8} = 0.25$$

$$\frac{ZC}{F} = \frac{500 \times 0.0032}{0.8} = 2.0$$

$2Z'C = 2 \times 500 \times 0.0032 = 3.2$

From Figure 6, $E_r/E_s = 1.7$, and from Table VI, $T/F = 2.6$

$T = 2.6 \times 0.8 = 2.08$

Substituting these values in the foregoing equation gives a voltage ratio of 1.37, as compared to a ratio of 1.37 obtained in a study of the same case on the analogue computer. Table IX is a summary of measured and calculated values for a number of special cases studied on the computer.

If the additional lines are terminated at the lightning arrester, the initial rate-of-rise of the voltage at the lightning arrester will be modified and the front F will be decreased. In this case the front F can be modified before entering Figure 6.

Table IX. Influence of Additional Lines on Transformer Voltage

Number of Additional Lines	Lines Terminated at	E_r'/E_s' Measured	E_r'/E_s' Calculated
0	transformer	1.70	
1		1.37	1.37
2		1.15	1.19
3		1.05	1.10
0	lightning arrester	1.70	
1		1.56	1.60
2		1.40	1.52
3		1.22	1.47

Note: Above values are based on overhead line surge impedances of 500 ohms, a capacitance of 0.0032 microfarad, and 200 feet between lightning arrester and transformer.

Let

F = front neglecting additional lines

F' = equivalent front including effect of additional lines

N = number of additional lines

Then

$$F' = \frac{N+2}{2} F$$

Assuming the same conditions as used in the above example, determine the voltage at the transformer with one additional line terminated at the lightning arrester.

$$F' = \frac{1+2}{2} \times 0.8 = 1.2 \text{ microseconds}$$

$$\frac{s/v}{F} = \frac{200/1{,}000}{1.2} = 0.167$$

From Figure 6, $E_r'/E_s' = 1.60$, which should be compared to the measured value of 1.56 given in Table IX. Comparisons between measured and calculated values are given in the table for 1, 2, and 3 additional lines. The calculated values are conservative because the influence of the additional lines on reflections from the transformer is neglected.

Lines Without Ground Wires

The data in Figure 6 can be used to estimate the transformer protection provided in cases where the overhead line is not protected with ground wires. The assumption of adequate shielding of the substation against direct strokes must still be made.

If the overhead line is not equipped with ground wires, the probability of strokes directly to a phase conductor in the vicinity of the station is high enough to warrant consideration. If such strokes occur, reflections from the station can prevent a line flashover, and the lightning arrester current can approach the stroke current in magnitude and rate-of-rise. In these cases, the initial rate-of-rise de/dt of the voltage at the lightning arrester location is equal to one-half the line surge impedance multiplied by the rate-of-rise of stroke current.

Discussion

H. W. Hartzell (Commonwealth Services Incorporated, Jackson, Mich.): This paper, while dealing largely with lightning-arrester protection for transformers, indirectly brings to attention the possible lack of protection resulting in many substations for equipment located near the circuit boundaries of these stations. This equipment includes the line entrance air break switches, busses, circuit breakers, and many other items that may be located at some distance from lightning arresters installed to protect the more costly transformers.

This problem was recognized many years ago in our organization as well as others and a great deal of consideration has been given to the protection of "boundary equipment" in substations, both large and small. Protection of this equipment, however, has not received the general attention which it would seem to deserve.

Tables II, III, and IV of the paper list suggested maximum distances between lightning arrester lead taps and protected transformers. A little consideration of these distances will show that it is often quite impractical to design substations so that all electrical components will be within the suggested circuit distances. In fact, it is sometimes very difficult to locate the lightning arresters within the suggested distances of the transformers themselves unless the lightning arresters are mounted on or directly adjacent to the transformers. This of course results in less effective protection for other substation equipment.

Protection of the other electric equipment then depends on how much risk of equipment failure the designer is willing to assume. His solution is usually a compromise based on the use of:

1. Standard basic impulse insulation levels.
2. Auxiliary surge protective equipment such as some form of spill gap.
3. Lightning arresters.
4. Various combinations of (1), (2), and (3).

The designer has a choice in his selection of insulation levels and may accordingly use higher levels for the boundary equipment in an effort to reduce the risk of failure. He may use valve-type lightning arresters located at each line entrance so as to provide additional protected areas within the station similar to that provided by the transformer lightning arresters. This will generally result in an excess of protection because not all surges coming into the station will have characteristics assumed by the authors of this paper and others when determining protection requirements for transformers. Only a small percentage of surges have these characteristics.

The spill gap then seems to have a logical place in the protective scheme for boundary equipment. Because its spark-over characteristics are somewhat similar to those of equipment depending primarily on air for insulation, the installation of gaps at line entrances to substations will provide protection areas around equipment which the severe steep front surges first encounter on coming into the station. A spill-over across the gap will then prevent a flashover in the circuit entrance equipment.

Our experience over a period of more than 15 years has shown that protection of both transformers and boundary equipment may be effectively achieved when transformer lightning arresters are applied in accordance with the principles suggested in this paper and simple line entrance gaps are applied for protection of the other station components. For most surges, the lightning arresters protect the whole station, even the line entrance gaps, and thereby prevent unnecessary line trip-outs. For the more occasional severe surge, a discharge of the line entrance gap provides the necessary boundary protection.

I. B. Johnson and **L. E. Saline** (General Electric Company, Schenectady, N. Y.): In view of differences of approach to the problem of lightning-arrester location it is of interest to compare the results in the authors' paper with those in a similar study by Carpenter, Johnson and Saline.[1] Whereas Witzke's and Bliss' results are initiated from traveling wave concepts and analysis, the results from the similar study referred to are derived from lumped circuit concepts and analysis.

For comparison, consider the separations from Table III of the paper for zero lightning arrester lead length and reduced transformer insulation with those given in Table III, of reference 1. These tabulated results in the reference paper were based on zero lightning arrester lead length and the preservation of a margin between the protective level held by the lightning arrester and a reduced transformer insulation level corresponding approximately to those given in a companion paper[2] for grounded neutral circuit. Table I of this discussion gives a comparative tabulation.

In arriving at these distances a number of different assumptions were made in each study. Among these was one of allowance of margin or no margin between the overvoltage appearing at the transformer due to separation and its equivalent voltage on the volt-time curve of the transformer insulation. Whereas it appears that Witzke and Bliss have assumed no margin, reference paper 1 assumed some margin as necessary. Consequently, if instead of holding the oscillatory overshoot at the transformer due to separation to 30 per cent it is allowed to reach 50 per cent, then the lightning arrester separations at 115 kv, 138 kv, and 161 kv become 55 feet, 65 feet, and 100 feet, respectively. These are to be compared with 53 feet, 67 feet, and 92 feet from the results by Witzke and Bliss.

Table I

System Voltage, Kv	Lightning Arrester Distance,* Feet (Witzke and Bliss)	Lightning Arrester Separation,** Feet (Carpenter, Johnson and Saline)
115	53	9
138	67	15
161	92	20
230	69	38
287	80	70

* Includes down lead to transformer.

** Does not include down lead to transformer.

Among the other differences in assumptions are these:

1. Magnitude and polarity of charge on the impulse capacitance of the transformer at the time of lightning arrester operation.
2. Magnitude and rate of rise of lightning arrester discharge currents particularly at the higher voltages.
3. Effect of transformer attenuation on the overvoltages at the transformer resulting from lightning arrester separation.

In general, the conclusions from the two studies are believed to be conservative inasmuch as they are based on an elementary circuit and do not include a bus having several connected circuits. At the higher voltages it may be that the results from the elementary circuit are also somewhat conservative insofar as they are derived from initiating conditions based on insufficient statistical data with regard to wave shapes of surges reaching stations and to magnitude and rates of rise of lightning arrester discharge currents. However, where costly equipment using reduced insulation is involved, conservatism is justified until and unless a larger field experience with reduced insulation, more complete statistical data on the nature of surges at the higher voltages, and more complete evaluation of the effect of various surge wave shapes applied to the insulation indicate otherwise.

J. R. Meador (General Electric Company, Pittsfield, Mass.): There are several points in the authors' paper that require further discussion and clarification. One of these is the question of margin between the factory impulse test on the transformer and the protected level in the field. Do the authors recommend zero margin between the transformer test voltage and the "disruptive effect" resulting from a severe lightning discharge?

The effect of the dynamic voltage on permissible separation between lightning arrester and transformer is not clear to me. In the example given under the section on Application of Computer Data, the length of circuit for limiting the maximum voltage at the transformer to 750 kv is 132 feet. If the dynamic voltage E_d is taken as zero, then

$E_s = 459.6$ kv
$E_v = 750$ kv
$E_v/E_s = 1.63$

From Figure 6,

$$\frac{S/V}{F} = 0.175$$

$$F = \frac{460}{500} = 0.92$$

$$S = 1{,}000 \times 0.92 \times 0.175 = 161 \text{ feet}$$

On this basis 161 feet of circuit will limit the maximum voltage at the transformer to 750 kv. Is this the proper interpretation?

The authors' use of an equation for "disruptive effect" is interesting but of very questionable accuracy. The complex phenomena involved in the breakdown of insulation by voltages of the type being considered here do not appear to be susceptible to such a simplified treatment. The results of our tests[1] on insulation samples gave very little hope that an equation of this form could be used with any confidence.

Until such time as the effect on insulation of superimposed oscillations is better understood, and more field data on rates of current rise through lightning arresters are obtained, it appears that considerable conservatism should be employed in separating the lightning arrester from the transformer. This is particularly true if the transformer has reduced insulation.

P. A. Abetti (General Electric Company, Pittsfield, Mass.): As in a previous paper,[1] the authors have represented the transformer as a pure capacitance, thereby neglecting the damping of the oscillations due to the losses which are present in the transformer winding, in the capacitances to ground, to shield, between coils and between turns.

The authors state that damping particularly affects oscillations subsequent to the first one. While this is undoubtedly true, reductions of practical importance are obtained also in the first peak, which is generally the highest. Carpenter, Johnson, and Saline[3] have taken into account this damping effect, by a 25 per cent reduction of the maximum voltages at the transformer. Do the authors think that such a factor should be taken into account? If they agree on some reduction factor, how would it modify the maximum lead lengths obtained in their investigation?

The surge capacitance, C, of the transformer was first obtained by L. F. Blume and A. Boyajian in 1919,[2] who stated

$$C = \sqrt{C_g C_s} = \frac{C_g}{\alpha} \text{ with } \alpha^2 = \frac{C_g}{C_s}$$

where C_g is the capacitance to ground and C_s the intercoil capacitance. These may be readily computed from the transformer design data. C is "considerably lower" than the capacitance to ground if $C_s << C_g$, or $\alpha >> 1$ which is not always the case.

The "suggested maximum distances between transformer and lightning arrester lead-tap when transformer has reduced insulation," as given by Table III of the paper, are plotted in Figure 1 of this discussion for zero lead length and for recommended lightning arrester levels. It appears very peculiar that separation should be less for 287-kv system voltage, than for 230 kv and 345 kv. It also appears questionable that separation should be almost the same for 230 kv and 345 kv. The corresponding data of Carpenter, Johnson, and Saline[3] show a consistent increase in separation as the system voltage increases, as may be seen from the dotted curve of Figure 1 of this discussion. In comparing the two curves, it must be remembered that Witzke's and Bliss' distances include the down lead to the transformer, but Carpenter's, Johnson's, and Saline's do not.

W. A. McMorris (General Electric Company, Pittsfield, Mass.): The qualitative results obtained by Carpenter, Johnson, and Saline[1] are in agreement with those obtained by Witzke and Bliss. They show that lightning arrester lead length and separation between lightning arresters and transformers should be minimized, and that in any particular case, the protective margin achieved will depend upon the wave shapes of the lightning discharges involved. The quantitative results obtained by the two groups are not in agreement because their calculations and tests have not started with the same assumptions.

Perhaps the weakest point in both studies is the lack of statistical field data on rates of rise of lightning currents discharged through lightning arresters in stations, and the rates of rise of voltage at stations prior to lightning-arrester sparkover. Such data have not been obtained in a quantity comparable to that obtained with the surge crest ammeter on the crest values of lightning-arrester discharge currents, because no equally accurate and low-cost measuring instruments have been available. There is great need for the development of such instruments which are low enough in cost to permit installation in large numbers, so that data can be obtained for a variety of representative operating conditions. It will then be necessary for the industry to review the wave shapes to be used for insulation coordination studies, in order to determine the best compromise between reliability and cost of apparatus.

The wave shapes assumed by Witzke and Bliss are probably as severe as will be encountered in most cases where recommended practices have been followed with regard to overhead ground wires, low footing resistance, and shielding of stations from direct strokes. If adequate shielding is not used, sneak strokes that get in under the ground wires may result in even more severe rates of rise of current than the 5,000 amperes per microsecond assumed by Carpenter, Johnson, and Saline.

R. L. Witzke and **T. J. Bliss**: Mr. Hartzell's discussion is very interesting in that it pre-

Figure 1. Maximum lightning arrester distance as a function of system voltage

sents the views of an operating company that has given careful study to the surge protection of station equipment. Our investigation was limited to the protection of transformers and did not include a consideration of other apparatus, such as circuit breakers, air switches, and so forth. We believe that individual studies of the larger stations are necessary to obtain the most economical protection, at least at this stage of the art.

The permissible separation distances given in the Carpenter, Johnson, and Saline paper[1] are very short by comparison to the values given in Table III of our paper. The discussion presented by I. B. Johnson and L. E. Saline attributes these differences to assumed margins. A careful analysis of the two papers will show that the assumptions relative to lightning arrester voltage, dynamic voltage, transformer capacitance, permissible transformer voltage and decrement are of more importance than margin. This fact is illustrated in Table II of this discussion for the case of a 450-kv BIL transformer protected with a 96-kv lightning arrester.

Procedure I is based on the Carpenter, Johnson, and Saline assumptions, whereas Procedure II is based on our assumptions. In both cases, protection is provided for an incoming surge having a rate-of-rise of 500 kv per microsecond, and the calculations are made by the method outlined in our paper.

The lightning arrester voltage under Procedure I was taken from Table III of the Carpenter, Johnson, and Saline paper. As dynamic voltage is neglected, E_t is equal to this lightning arrester voltage. The ZC/F ratio is based on the assumed 1,000 micromicrofarad transformer capacitance used in the section on Relation of Overvoltage to Volt-Time Characteristic of the Apparatus of the above paper. Carpenter, Johnson, and Saline limited the oscillation in the voltage at the transformer to 30 per cent, but allowed for 25 per cent damping. The undamped oscillation permitted is therefore 40 per cent, making E_T/E_s equal to 1.40 when attenuation is neglected. Referring to Figure 6 of our paper, a ZC/F ratio of 0.625 and an E_T/E_s ratio of 1.4 gives an $(s/v)/F$ ratio of 0.10, from which we obtain a separation distance of 72 feet.

The lightning arrester voltage under Procedure II assumes an overhead line having a full-wave insulation level of 760 kv, and is calculated as outlined in our paper. As we include dynamic voltage, E_s is higher than the lightning arrester voltage by 94 kv, the crest line-to-neutral voltage of a 115-kv system. Adding this dynamic voltage to 520 kv, the chopped-wave level of the assumed transformer, gives an E_t value of 614 kv. As data are not generally available on the effective surge capacitance of transformers, we chose to use the upper curve in Figure 6 of our paper, this curve being based on a ZC/F ratio of 4.0 in the region of interest in the present comparison. We also chose to neglect loss because this varies with the circuit and transformer characteristics, and because insufficient data are available on this factor. With these assumptions, we obtain a separation distance of only 55 feet under Procedure II as compared to 72 feet under Procedure I. We, therefore, conclude that our procedure is more conservative even though we include no margin.

Table II

	Procedure I	Procedure II
E_{arr}	360 kv	341 kv
E_d	0	94
E_s	360	435
F	0.72 microsecond	0.87 microsecond
E_t	468 kv	614 kv
C	1,000 micromicrofarads	
$\frac{ZC}{F}$	0.625	4.0
E_T/E_s (with loss)	1.30	
E_T/E_s (no loss)	1.40	1.41
$\frac{s/v}{F}$	0.10	0.063
s	72 feet	55 feet

It should be noted that the foregoing comparison is based on providing protection against an incoming surge having a rate-of-rise of 500 kv per microsecond. It is our opinion that some assumption must be made relative to the incoming surge before permissible separation distances can be evaluated. Carpenter, Johnson, and Saline neglected the all-important transients that occur prior to the time the lightning arrester gap operates, which was necessary in the absence of assumptions regarding the incoming surge. The short distances given in the section, on Relation of Overvoltage to Volt-Time Characteristic of the Apparatus of their paper, are due to neglecting these transients rather than to including margin.

Mr. Meador's interpretation of our application procedures is correct. If dynamic voltage is neglected the separation distances will be longer. We, however, feel that dynamic voltage should be considered if conservative results are to be obtained. We agree that the breakdown of insulation is a complex phenomena that cannot be accurately represented by a simple equation. As stated in our paper, the industry is in need of an acceptable method of evaluating the influence of surge voltages of nonstandard wave shape on electric apparatus, and that the method finally adopted should be substantiated by laboratory test results. The laboratory tests, however, must be more extensive than the major insulation tests in the Clem, Meador, Rudge, Powell paper.[2]

Our results neglect the damping introduced by the transformer as mentioned by Mr. Abetti. These losses vary with the circuit and transformer characteristics, and should not be given too much weight in surge protection applications until more test data are available. The results in Table III of our paper do not show a consistent increase in the permissible separation distances because the established basic insulation levels are inconsistent. It should be noted that the BIL-to-system voltage ratios used in Table III are 3.92, 3.66, and 3.76 for system voltages of 230, 287, and 345 kv, respectively. The lower ratio at 287 kv is reflected in our results, but not in the Carpenter, Johnson, and Saline paper.

Mr. McMorris emphasizes the fact that the weakest point in studies such as reported in our paper is the lack of statistical field data on the characteristics of surges that reach stations. Until such data are available, protection must be based on reasonable assumptions that give due consideration to experience.

Development of the Standard for Neutral Grounding Devices

J. E. CLEM
FELLOW AIEE

PRIOR to the time AIEE Standard number 32[1] was first published there were no standards for neutral grounding devices, information on them being included in other standards as supplementary information. There was a definite need to have all the material in reference to grounding devices in the same place and AIEE Standard number 32 was prepared to satisfy this need.

The standard for neutral grounding devices is different from other standards in that it is a functional standard. It is a standard covering the characteristics of several types of devices when used for grounding purposes. The purpose of this paper is to outline briefly the factors reviewed in the preparation of the standard for neutral grounding devices.

When the group appointed to prepare the standard took up its work, it quickly became evident that the terminology required some clarification.

The definition of "rated circuit voltage" ASA C42-15.10.100[2] was considered to be definitely in error on two counts:

1. Systems do not have a rated circuit voltage in the same sense that equipment has a rated voltage.

2. According to the definition, the rated circuit voltage of a system would change each time a transformer was connected to the system which had a secondary voltage higher than the transformer already there.

Accordingly, the group took a realistic attitude and discarded the term and its definition completely. The various systems were identified by another term "circuit voltage class", which was used in the selection of insulation class designations for neutral grounding devices. This action culminated with the later adoption by the Edison Electric Institute—National Electrical Manufacturers Association Joint Committee in Preferred Voltage Ratings for A-C Systems and Equipment[3] of the term "nominal system voltage" for the purpose of convenient designation of the voltage class of a circuit or system.

The terms indicating the various methods of grounding were selected and defined. The term "effectively grounded" was tied down securely and made quantitative by putting numbers in the definition to associate the term with limiting impedance ratios.

Before the standard was written, it was customary to base the thermal and mechanical short-time current ratings of neutral grounding devices on the "rms value of the current, including the d-c component." This appeared to be an unwieldy manner of handling this simple feature. The heating of a neutral grounding device, for the rating times considered in this standard, is practically independent of the initial offset of the ground fault current flowing through the device.

The mechanical forces depend upon the maximum crest value of the first displaced cycle. Since the decrement of the fault current may vary, not only among systems, but also among various points on the same system, some assumption of offset for the first cycle was required to establish standards for the mechanical current rating.

When a fault occurs, the fault current is initially a function of the subtransient reactance and is displaced giving rise to the d-c transient. After a few cycles, it is a function of the transient reactance. Although a displaced current will have a greater heating effect than a symmetrical current, the effect is practically negligible when the time element is ten seconds or more. Therefore, it became obvious that the use of the rms value of the symmetrical fault current, calculated using the transient reactance, for the thermal current rating was not only reasonable but also logical.

There was considerable discussion when the proposal was made to express the mechanical current rating on the rms value of the fault current and accordingly on same basis as the thermal current rating. The reason for this proposal is this: calculations of the fault current, for the determination of the thermal current rating, are made in a manner for which the result is obtained as an rms symmetrical current. If this value of fault current is used without modification but with an assumed value of offset, the procedure is simplified.

The use of the rms value of fault current to express both the thermal current rating and the mechanical current rating is simple and direct. To do this it was necessary to stipulate in the standard that the device be capable of withstanding the mechanical forces set up by the current on the basis that the current wave is completely offset. In addition, it was necessary to make allowance for the fact that the calculations of fault current for the thermal current rating are made using the transient reactance of the generators, while the fault current which determines the mechanical forces is determined by the subtransient reactance, and accordingly is higher during the first few cycles. This difference was checked for several representative cases and it was found that a difference of 20 per cent in the two values of current would include a large enough proportion of possible occurrences to justify its use in the standard. Accordingly, in the interest of simplification, the standard requires that the mechanical current rating of a neutral grounding device be 1.2 times the thermal current rating.

Paper 50-154, recommended by the AIEE Protective Devices Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 13, 1950; made available for printing April 17, 1950.

J. E. CLEM is with the General Electric Company, Schenectady, N. Y.

The voltage rating of neutral grounding devices was carefully analyzed. It seemed reasonable to use, as the basis of the voltage rating, the voltage developed across the device during a fault. There were two cases for which an exception appeared justified. For resistor neutral grounding devices it was thought desirable to make the voltage rating the same as the line-to-neutral voltage of the circuit on which it was used whenever the impedance voltage at 25 degrees Centigrade exceeded 80 per cent of the circuit line-to-neutral voltage. This was done because of the increase in resistance due to increase of temperature. And quite obviously, the voltage rating of a grounding transformer should be the same as the line-to-line voltage of the circuit on which it is used, because it is directly connected to the circuit.

The question of the time rating involved much discussion. Prior to the writing of the standard, neutral grounding devices had been specified for various time intervals between ten seconds and two minutes. A careful review of the essential performance requirements of the devices indicated that a rated time of one minute would be adequate for all cases except one and for all devices except ground fault neutralizers. The review indicated that neutral grounding devices used for grounding the neutral of generators need not require in many instances, the 1-minute time rating, a 10-second rating being sufficient.

The review also showed that practice in the use of ground fault neutralizers required a short-time rating longer than one minute, and a long-time rating shorter than continuous. Ten minutes was chosen for the short-time rating and 90 days for the long time, the latter being designated as "extended time."

Ground fault neutralizers are required to be capable of carrying continuously a circulating current equal to 30 per cent of their rating without exceeding a 55-degree Centigrade rise. This results in a well-co-ordinated thermal design between the continuous capability and the time rating. When the standard was being prepared there was some question as to whether this value of circulating current might be too small, or too large. Consequently a survey was undertaken after the standard was finished to answer this question. The results of the survey have been reported[4] and indicate that the value chosen for the standard was about the optimum, being high enough to cover nearly all the cases and not so low as to require costly transpositions. The investigation included economic factors.

In establishing the temperature limits, a new concept was introduced for those devices using class-A and class-B insulation. Previously equipment standards merely required that the equipment be capable of withstanding a specified value of fault current for a specified time. An analysis was made to check the relative aging during the heating-up period, the specified time, and the cooling-off period, which revealed some very startling results.

For example, one standard states that a fault current of 25 times rated value must be withstood for two seconds, and 16.6 times for four seconds, and this is coupled with the requirement that the starting temperature be assumed as 95 degrees Centigrade and the limiting temperature be 250 degrees Centigrade for class-A material. Nothing is said about how often this may occur. It is absurd to say that 250 degrees Centigrade for four seconds produced by 16.6 times current is no worse than 250 degrees Centigrade for two seconds produced by 25 times current, and it is equally absurd to neglect the frequency of occurrence.

Actually, there were some who maintained that the 250-degrees Centigrade temperature for four seconds should be incorporated in the standard for neutral grounding devices, because its presence in the other standard indicated that "experience had proven it to be satisfactory." It was a simple matter to show that a temperature of 250 degrees Centigrade for four seconds would cause, in one occurrence, the insulation to deteriorate slightly more than in one year's normal operation. Further, calculations proved conclusively that the equipment in question had thermal characteristics such that it was impossible to attain the 250-degrees Centigrade limiting temperature at the specified current, even if the fault continued for the time mentioned in the standard.

It was easy to demonstrate that most, about 95 per cent usually, of the aging of the insulation occurred during the cooling period of the temperature cycle. The obvious next step is the recognition of the fact that a device that has a slow rate of cooling should have a lower limiting temperature, if the aging in the two cases is to be comparable.

Prior to the initiation of the work on this standard, it was commonly accepted throughout the industry that cooling was always a logarithmic function. This is true only for those devices for which the temperature rise is directly proportional to the losses. However, the temperature rise of devices immersed in a cooling liquid is not directly proportional to the losses but varies as an exponential function with the exponent different from unity. Thus

$$\theta = kw^n$$

In this equation n is always less than unity down to a value of about 0.7. Because of this neither the heating nor the cooling is a logarithmic function.

Once the concept that the rate of cooling and the permissible maximum temperature should be correlated, it was easy to pass on to the next forward step of setting the maximum temperature limitation on the basis of the relative aging over a definite period of time. Aging data[5] for class-A insulation as determined by laboratory tests at various temperatures are available. The relative aging is based upon the reduction in mechanical strength. This information does not enable one to estimate the useful life of a transformer or of any other equipment. It does enable one to estimate how much more rapidly the insulation used in equipment will lose its mechanical strength when the temperature to which it is subjected is increased.

It has been customary to consider that the rate of aging for class-A insulation when used in transformers doubles with each 8-degrees Centigrade increase in temperature. The information in reference 5 indicates that the temperature increment which doubles the rate of aging at 95 degrees Centigrade is much less than 8 degrees Centigrade. The series of temperature increments, 2, 2.5, 3, 3.5, 4, 5, 6, 7, 8, . . ., starting at 95 degrees Centigrade, gives closely the same over-all increase in rate of aging for a wide range in temperature as does the data in reference 5. Rate-of-aging curves were prepared using these increments, and extending over the range of temperatures under consideration.

The exponent n of the heating characteristic for liquid-insulated devices is not constant. Apparently it will increase when the insulation thickness is increased, and apparently it is reduced at higher temperatures because of the lowered viscosity of the oil. All such factors were considered when the cooling curves upon which the aging calculations, used in establishing the temperature limits, were prepared. Calculations were made of both the heating and cooling periods and compared with test results for different conductors, thickness of insulation, and temperatures of the cooling oil. The analytical formula was first used, but was modified as the study progressed by empirical factors and procedure until the agreement was very, very close.

Considerable thought was given to the question of the relative aging upon which to base the temperature limits. This would be dependent, of course, upon the number of times the device might be called upon to function and upon the relative loss of life which might be considered reasonable. An investigation was made and it appeared that ten operations per year would be sufficient to cover all except the most severe operating conditions. It seemed reasonable also to expect these devices to have about the same life expectancy as power and distribution transformers.

The rate-of-aging curves, and the heating and cooling curves, were used together to establish temperature limits and the associated initial rate of cooling, such that ten events per year would give about the same loss of life in one year as occurs in a transformer when operated at full load in a 30-degrees Centigrade ambient temperature for one year.

Prior to the development of the standard it was customary, in checking the temperature rise on the occurrence of a fault, to neglect the insulation associated with the conductor and to assume that all the heat was stored in the copper. This assumption was conservative for the heating-up period, but would have been suicidal for the cooling period. Even when the insulation was considered, the formula used for the combined thermal capacity had no sound basis.

In working out the heating and cooling curves previously mentioned, an empirical formula for the thermal capacity of the copper conductor and its associated insulation was developed. The development of this formula was closely and directly associated with the development of the empirically modified heating and cooling formulas previously mentioned. Since its use with the correct method of calculating heating and cooling curves gives correct results, it is reasonably and logically considered to be correct for the high-temperature conditions allowed in the standard for neutral grounding devices.

Since limiting temperature is dependent upon the rate of cooling, it is necessary to have a uniform method of quickly checking the cooling rate. This is affected by several factors, some of which, such as the temperature rise at the start of the cooling period, can be directly evaluated, and others, such as the exponent of the heating characteristic, cannot. Accordingly, a simple expression containing an empirical factor was developed. This expression gives very good results over the range of temperatures for which it is used. The use of this empirical formula provides a ready and simple means of making sure that the thermal design of any specific device is reasonably correct.

The establishment of a limiting maximum temperature and the corresponding cooling required an extended analytical investigation, together with an extensive experimental investigation. Part of this experimental and analytical investigation was reported by Montsinger and Clem[6] and part by Montsinger and Halsey.[7]

An outline of some of the analytical work is given in the appendix to this paper.

Methods of demonstrating that the temperature limits are fulfilled in the design came in for considerable discussion. It was agreed that the 10-second and 1-minute ratings could be demonstrated adequately by calculations and that the 10-minute and extended time ratings should be demonstrated by tests. Therefore, formulas for calculating the temperature rise were developed and placed in the standard for the various conditions and types of devices. To be on the conservative side, these calculations are made on the basis of all heat stored and with the eddy-current loss neglected. When eddy currents are present the increase in resistance as the temperature rises reduces the eddy-current portion of the losses. The high-temperature rises allowed for neutral grounding devices results in a high rate of cooling. Accordingly, the requirement that a cooling curve be taken on the temperature on each device was included in the standard as applicable to the 10-second and the extended time ratings.

Prior to the development of this standard, the problem of selecting the proper dielectric test was a rather difficult one. This problem was analyzed for a considerable time and tabulations were prepared with accompanying instructions which will result in the selection of the same dielectric test irrespective of who makes the selection.

As mentioned earlier, the standard for neutral grounding devices is on a somewhat different basis than other equipment standards, because the functional performance of the device is of prime importance. There has been included in the standard a considerable amount of information on the selection and application of neutral grounding devices. It was felt desirable to do this because the frequency of use of these devices is much less than of other equipment, and with this information available in the body of the standard the application engineer will not be called upon to do research work elsewhere.

The correlation of the temperature limits with the rate of cooling and the reliability of the empirical expressions for the thermal capacity of the conductor together with its associated insulation, and for the rate of cooling, places the thermal design of neutral grounding devices on a sound, uniform, and clean-cut engineering and commercial basis. The engineering establishment of varying limiting temperatures, as dependent upon the rate of cooling and a reasonable aging for a specified time, is an outstanding development.

It is felt that this standard is a forward contribution to the list of standards prepared by the Institute and that by adopting the principle of selecting the maximum limiting temperature on the basis of the rate of cooling, a precedent has been set which should be followed in the standards for other types of equipment.

Appendix

Heating and Cooling Curves—General Equation

At any point on the heating curve of a device, the increment in temperature will be determined by the energy supplied in the increment of time and the thermal capacity. As an analytical expression

$$\Delta\theta = \frac{(W_s - W_r)\,\Delta t}{C}$$

where

$\Delta\theta$ = increment in temperature
W_s = rate of heat supply
W_r = rate of heat loss
Δt = increment of time
C = thermal capacity, properly associated with the units in which W_s and W_0 are given

$$W_s = (1 + \alpha_0\theta)\,W_0$$

where

α_0 = temperature coefficient of resistance at the starting temperature, θ_0
θ = temperature increase above the starting temperature at time t
W_0 = initial watts input at zero time

$$W_r = K\theta^n$$

where

K = empirical constant, depending upon the design
n = empirical exponent, varies from about 1.5 to 1.0 depending upon the design, temperature, and possibly other factors

Neither K nor n are themselves constant over the range of temperatures encountered in neutral grounding device design, but are essentially constant for the temperature range in the design of transformers.

Cooling Curve

The differential equation

$$d\theta = \frac{-W_r}{C}\,dt$$

The solution

$$t = \frac{C\theta_1}{W_1}\,\frac{1}{1-n}\,(1-r^{1-n})$$

where

θ_1 = temperature rise at start of cooling period
W_1 = watts loss corresponding to θ
r = ratio of θ to θ_1

The writer first derived this expression many years ago and quickly found that, while it applied very well for the usual temperatures of transformer windings and oil, it became increasingly unreliable as the temperatures increased.

If n is unity, the solution is

$$t = \frac{C\theta_1}{W_1}\log\frac{\theta_1}{\theta}$$

$$\theta = \theta_1 e^{-at}$$

$$a = \frac{W_1}{C\theta_1}$$

These are the so-called standard cooling curve equations and the quantity a represents what has been referred to as the time constant.

A better way of calculating a cooling curve at high temperatures is to determine the heating characteristic, that is, the curve showing the temperature rise θ as a function of watts loss W_r. Then use the equation

$$\Delta t = -\frac{C}{W_r}\Delta\theta$$

and take reasonably small decrements in θ, reading W_r for the midpoint of the decrement, at the same time compensating the thermal capacitance for the change in temperature. This is the method that was used in deriving the temperature limits and the required rate of cooling which were adopted for the standard.

Heating Curves-Constant Current

No Radiation—No Eddy Current

The differential equation

$$d\theta = \frac{W_0}{C}\,dt$$

The solution

$$t = \frac{C}{\alpha_0 W_0}\log(1+\alpha_0\theta)$$

$$\theta = \frac{1}{\alpha_0}(e^{at}-1)$$

$$a = \frac{\alpha_0 W_0}{C}$$

The translation of these expressions into those given in the standard is simple and straightforward.

No Radiation—with Eddy Current

The differential equation

$$d\theta = \left\{(1-m)(1+\alpha_0\theta)W_0 + \frac{mW_0}{1+\alpha_0\theta}\right\}\frac{dt}{C}$$

where

m = per-unit eddy-current loss, referred to the total initial loss W_0

The solution

$$t = \frac{1}{a}\log\left\{(1-m)(1+\alpha_0\theta)^2+m\right\}$$

$$\theta = \frac{1}{\alpha_0}\left\{\sqrt{\frac{e^{at}-m}{1-m}}-1\right\}$$

$$a = \frac{2\alpha_0(1-m)W_0}{C}$$

A comparison of the equation for the time given here with that given for the preceding case shows quite clearly that the presence of eddy currents does increase the time to attain any specified temperature. Therefore, neglecting the eddy current loss gives conservative results.

Radiation—No Eddy Current

The differential equation, when the exponent n is taken as unity

$$d\theta = \left\{(1+\alpha_0\theta)W_0 - K\theta\right\}\frac{dt}{C}$$

The solution

$$t = \frac{\theta_1 C}{W_0}\log\frac{1}{1-r}$$

$$\theta = \theta_1(1-e^{-at})$$

In these equations

θ_1 = ultimate temperature rise
r = ratio of temperature θ at time t to ultimate temperature rise $= \frac{\theta}{\theta_1}$

$$a = \frac{W_0}{\theta_1 C}$$

Radiation—with Eddy-Current Loss

Analytical

The differential equation, when the exponent n is taken as unity

$$d\theta = \left\{\frac{(1-m_1)(1+\alpha_0\theta)}{1+\alpha_0\theta_1} + \frac{m_1(1+\alpha_0\theta_1)}{1+\alpha_0\theta} - \frac{\theta}{\theta_1}\right\}\times\frac{W_1}{C}\,dt$$

In this equation m_1 is now the per-unit eddy-current loss referred to the total ultimate loss W_1.

The solution

$$t = \frac{C\theta_1(1+\alpha_0\theta_1)}{W_1(1+2m_1\alpha_0\theta_1)}\times\left\{\log\frac{1}{1-r} + \frac{m_1\alpha_0\theta_1}{1+m_1\alpha_0\theta_1}\log\frac{a}{a-cr}\right\}$$

$$a = 1+2m\alpha_0\theta_1+m(\alpha_0\theta_1)^2$$

$$c = -\alpha_0\theta_1 - m(\alpha_0\theta_1)^2$$

Step by Step

The differential equation may be put in the form

$$\Delta t = \frac{C}{(1-m)(1+\alpha_0\theta)W_0 + \frac{mW_0}{1+\alpha_0\theta} - W_r}\,\Delta\theta$$

As was done for the cooling curve, the procedure is to establish the heating characteristic, take reasonable increments of temperature, determine the heat supplied and radiated, adjust the thermal capacity for the actual temperature, and then calculate the corresponding increment of time.

The step-by-step method was used for the calculations for the oil-immersed devices, and additional spot checks by the analytical method were obtained for the dry-type devices.

Heating Curve—Constant Voltage

The differential equation

$$d\theta = \frac{W_0}{C(1+\alpha_0\theta)}\,dt$$

The solution

$$t = \frac{C\theta}{W_0\left(1+\frac{\alpha_0\theta}{2}\right)}\,dt$$

$$\theta = \frac{1}{\alpha_0}\left\{\sqrt{\left(1+\frac{2\alpha_0 W_0 t}{C}\right)}-1\right\}$$

In these equations the eddy-current loss has been neglected and the translation into the form given in the standard is simple and straightforward.

Indicating Instruments at the Servomechanism Frequencies

WILSON S. PRITCHETT
ASSOCIATE AIEE

ROBERT M. SAUNDERS
MEMBER AIEE

Synopsis: Tests on indicating instruments excited with sinusoidal signals at the servomechanism frequencies show that under certain conditions they are the same useful and time-saving tools as when used at the power frequencies. These conditions are determined by the motional characteristics of the instrument and the desired accuracy. This paper describes the performance of conventional indicating instruments at these low frequencies, discusses what can be done to these instruments to make them more suitable for this service, and gives one example of what can be expected when an indicating instrument is designed expressly for servo system use.

WITH the advancing application of sinusoidal analysis to servo systems, the need has arisen for instruments that will measure a-c steady-state quantities in the frequency range of usual servo operation, either by use of conventional portable instruments or by the development of new instruments. At the present time the oscillograph and oscilloscope are the most commonly used tools in the analysis of servo systems. If the indicating instrument could be used, it would make the analysis of oscillograms unnecessary, and would thereby represent a considerable saving in the time required for a-c steady-state servo analysis.

Most commercial a-c indicating instruments are designed for optimum performance in the range from 25 to 133 cycles per second. As the frequency applied to the terminals of such instruments is reduced, the behavior of the instrument is characterized by three zones:

Zone A—Where the pointer remains motionless or has a small excursion on either side of the average deflection.

Zone B—Where the pointer follows the impressed wave without amplitude or phase angle error.

Zone C—The zone lying between zones A and B.

In most instruments zone A extends downward from the power frequencies and the readings represent the effective values of the impressed wave, while zone B extends upward from zero frequency or direct current and the maximum reading of the instrument represents the maximum value of the wave. Either zone A or B operation of the instrument will result in reliable indications of either the maximum or the effective value of the wave in question. Zone C operation is completely unreliable. Frequently a-c instruments which have a low stated error on direct currents give a larger deflection on one half than on the other half of the cycle when used in zone B, but the average of the two maximum readings usually can be used. It is the object of this paper to: determine the ranges of zones A, B, and C in commercial instruments available today; explore the means of modifying conventional instruments toward extending zone A downward, zone B upward, and compressing zone C; and to consider the design features of an instrument that will extend zone A beyond that now encountered in conventional instruments.

Conventional Instrument Characteristics

The amplitude response versus frequency characteristic of a given instrument will provide one with the information needed to determine where the described zones lie.

In this paper the per-unit change in scale reading is defined as the ratio of the actual change in reading to the reading corresponding to the maximum value of the impressed electrical quantity. When the per-unit change in scale reading is unity, the instrument is following the impressed wave precisely without amplitude error, as described for zone B. As the frequency of the impressed wave increases, although the amplitude remains constant, the per-unit response begins to fall off until the per-unit change in reading becomes very small, say within approximately 5 per cent; this is defined as the beginning of zone A which then extends upward to the power frequencies

Figure 1 shows the amplitude response characteristics of several conventional instruments when subjected to such a constant amplitude but varying frequency voltage. The ideal instrument, whose characteristic curve is shown at the left of Figure 1, would have a zone C of negligible width; thus the width of zone C becomes a figure of merit for instruments contemplated in this service. It is noted that the electrodynamometer instrument follows the wave up to 0.07 cycle per second and then begins to drop off. At 1.0 cycle per second, the excursion on either side of the average reading is within 5 per cent so that the average position of the pointer now is indicating the effective value of the wave. Thus for this instrument zone A extends downward to 1.0 cycle per second; zone B extends upward to 0.07 cycle per second, and zone C extends from 0.07 to 1.0 cycle per second. The D'Arsonval instrument (which has no zone A) and the full-wave rectifier instrument have characteristics very similar to each other even though the applied torque waves are not the same function. Zone C is about two decades wide for these instruments. Since zone B extends to the same upper frequency as

Paper 50-155, recommended by the AIEE Instruments and Measurements Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 13, 1950; made available for printing April 17, 1950.

WILSON S. PRITCHETT and ROBERT M. SAUNDERS are both with the Division of Electrical Engineering, University of California, Berkeley, Calif.

The authors wish to express their appreciation to F. F. Davis for his many contributions to the design and construction of the low-frequency instrument described herein.

Figure 1. Amplitude response versus frequency characteristics for conventional instruments, the ideal instrument, and the low-frequency instrument described in the paper. The instruments associated with each curve are described in Table I

Figure 2. Phase angle versus frequency characteristics for some of the instruments shown in Figure 1

for the electrodynamometer type, these instruments are not as attractive since their zone *C* is much wider. The general characteristic of the moving vane instrument is shown as curve *E1* in Figure 1. The particular instrument shown here is one which was chosen for later modification. The thermocouple instrument was selected because of its relatively long zone *A* although its zone *C* is about five octaves. The instrument whose design is described later in this paper is shown for comparison purposes as curve *F*, and shows what can be expected from an instrument expressly designed for this service. It should be pointed out that the ordinate is plotted in terms of change in scale reading, not change in deflection. In this paper deflection is defined as the angle of motion of the movement, whereas the scale readings are those values which appear on the face of the instrument. If the curves were plotted in terms of the change in deflection, they would all be of the same general type as that for the D'Arsonval instrument. However, because of the nonlinear scales on a-c instruments, the curve of change in reading is very steep at the upper end.

Table I summarizes and collects the pertinent data for the various instruments tested. These instruments were believed to be typical examples of the portable instruments found in most laboratories. It was found that all tests of instruments of a particular type (for example, electrodynamometer) resulted in the same general curve although the curves might be displaced slightly to the right or left depending upon the manufacturer.

All but one of the instruments tested used eddy current damping of some type, and an auxiliary additional means of damping was employed as described in the column labeled "Special Damping Medium." Instrument *F* solely employed an oil whose viscosity was 38 seconds, Saybolt Universal Viscosity (SUV) at 100 degrees Fahrenheit. The time constant is defined as the time required for the deflection to reduce to 37 per cent of its initial value.

In most cases the amplitude response characteristic is of more significance; however, in the interest of completeness, the curves showing the angle of lag of the maximum deflection of the pointer with respect to the impressed wave as a

Figure 4 (right). Mechanical arrangement of the fixed and moving coils of the electrodynamometer instrument constructed with a large moment of inertia for use on low frequencies. The tank, whose size is 11 inches long, 8 inches wide, and 5 inches deep, is not shown

function of frequency are included in Figure 2.

It is possible to compute the characteristics shown in Figure 1 and 2; however, these instruments probably will be used for investigation of control system response to a-c signals. In such cases it is quite likely that there will be a low-frequency oscillator available so that the actual frequency response curve can be obtained for the contemplated instrument. This procedure is considered to be somewhat simpler than calculating the curve. As is shown in equation 8, Appendix I, the upper and lower limits of the deflection of an electrodynamometer movement are obtainable from

$$\theta = I_f I_M \frac{dM}{d\theta} \left\{ \frac{\cos\phi}{K} + \frac{1}{\sqrt{(K-4\omega^2 J)^2 + (2\omega D)^2}} \sin(2\omega t + \lambda) \right\} \quad (8)$$

The first term represents the mean deflection whereas the last term represents the excursion on either side of the mean. Graybeal[1] has examined this latter term in considerable detail, and one may make use of his work to reduce the labor involved in calculating the response curves. In order to use Graybeal's curves, it is necessary to know the natural frequency and the relative damping. The natural frequency can be obtained in most cases by removing the lid of the air damping box or by removing the damping magnets so that the number of oscillations per given length of time can be found. In some cases the relative damping can be determined by use of Graybeal's Figures 8 and 9 for which one must know the ratio of the successive maximum swings, if oscillatory, or the time it takes for the deflection of the instrument to become 50 and 25 per cent of the initial value if it is overdamped. In some cases this relative damping cannot be ascertained without the use of special equipment because the instrument may move too fast for visual observation. However, it may be assumed that β lies between 0.7 and 1.0 for most instruments since the manufacturers make every attempt to cause their instruments to register the final reading in a minimum length of time and with minimum oscillation.

Calculated points for the curve pertaining to the electrodynamometer instrument are shown as circles in Figure 1. In the case of the moving vane instrument or any other in which the torque is a nonsimple function of the position of the movement, the calculations become involved. However, one may sometimes make the simplifying assumption that the torque varies as the square of the applied current, and obtain curves that check reasonably well with test. Such a set of points for a moving vane in air are plotted as triangles in Figure 1. It will be noted that one may calculate curves closely approximating the test curves.

Modifications to Conventional Instruments

As was mentioned previously, there are some modifications that can be made to conventional instruments that will shift zones *A*, *B*, and *C* to the left. Damping is one such modification. Curves *E1*, *E2*, *E3*, of Figure 3 show how zone *A* can be extended as the time constant of a given instrument is increased from 1.2 to 23 seconds. Curves *E2* and *E3* are for liquid damping, the whole instrument being set in insulating oils of 10 and 200 SUV. The authors feel that increasing the damping is not an especially desirable method of extending zone *A* because zone *C* becomes extremely wide, and the transient response is very much impaired when heavy damping is employed. In collecting the data for curve *E3*, it was noted that it took nearly five minutes for the needle to come to its final deflection after being energized with a 1-cycle-per-second wave. Ordinarily this extremely long time constant cannot be tolerated.

Curves *E4*, *E5*, and *E6* of Figure 3 show the effects of decreasing the natural frequency by increasing the moment of inertia. As is shown by Graybeal[1] the natural frequency

$$f_n = \frac{1}{2\pi}\sqrt{\frac{K}{J}} \quad (1)$$

where K is the spring constant and J is the moment of inertia of the movement.

Since, for a given instrument, the spring constant cannot be reduced without jeopardizing the electrical to frictional torque ratio, the only other possibility is to increase the moment of inertia. However, the increase in that quantity can only be effected by adding weight to a movement. This results in added load on the bearings, a condition that will lead also to faulty operation. Hence, it is concluded that modification to conventional instruments is not as attractive as designing an instrument for use at the frequencies encountered.

A Special Low-Frequency Instrument

An instrument overcoming the objections mentioned previously and having a Zone A throughout Zone C of conventional a-c instruments has been constructed. At the outset it was decided to use construction as nearly conventional as possible and to employ commonly available springs, pivots, and jewels. Rapid response together with low per-unit change in scale reading was afforded by a high moment of inertia moving system with damping slightly below critical.

Since the moment of inertia and consequently the weight required was many times that of conventional instruments, means other than jewels and pivots alone were needed to support the extra burden.

Table II. Comparison of Mechanical Contants of Conventional Electrodynamometer Instrument with Low-Frequency Instrument

	Conventional Instrument	Low Frequency
Spring constant, gm-cm/radian	0.18	0.18
Weight of moving system, gram		
In air	3.2	215
On bottom pivot	3.2	2 (approx)
Undamped natural periods, seconds	1.0	23*
Moment of inertia, gm-cm²	4.5*	2,300

* Computed from measured constants.

This was accomplished by winding the moving coils upon a hollow bakelite cylinder and immersing the entire instrument mechanism in an insulating liquid. The cylinder was designed so that the residual weight of the moving system when submerged was well within the normal capacity of the pivots and so that the moment of inertia was correct for the springs used. Table II compares the mechanical constants of the low-frequency instrument with those of a high-quality commercially available instrument.

Appendix II describes the design requirements which led to the choice of the mechanical constants given. Use of the electrodynamometer principle permitted calibration of the low-frequency instrument on d-c and afforded greater flexibility in application. Advantage was taken of the needed weight of the moving system to use as many turns of comparatively large wire as possible since the pivots were not required to carry the burden. The low frequencies for which the instrument was intended made the resulting large inductance acceptable. Both of these factors offered uncommon possibilities in securing excellent sensitivity for instruments of the electrodynamometer type. In this instance, it was possible to design the moving coil for both good current sensitivity and good voltage sensitivity. That is, the number of turns could be made large enough to permit the instrument to be connected as a sensitive voltmeter and at the same time the resistance could be kept low enough to permit the instrument to be connected as a low-loss ammeter. A separate set of fixed coils, however, was required for each of the two connections. If the moving coil had been designed for either the voltmeter or the ammeter alone the sensitivity could have been appreciably improved. Figure 4 shows the arrangement of the fixed and moving coils for the compromise design.

Since instrument transformers are not suitable for use at the very low frequencies it was decided to provide four ranges on both the voltmeter and ammeter connections. Accordingly, four multipliers for the voltmeter were required. Four shunts together with eight current coils which were wound to have approximately the same average position about the moving coil were required for the ammeter. Heavy brass terminals with links were provided to make the desired series, parallel, or series-parallel connections of the current coils.

Figure 5 shows the schematic diagram and the circuit constants of this low-frequency electrodynamometer. The series connection of the current coils is shown in the figure. It is seen that additional provisions have been made for connecting the instrument either as a multiple-range wattmeter or as a single-range milliammeter. Also the instrument can be used as a separately excited electrodynamometer for harmonic analysis or phase angle studies. The small resistor connected to the wattmeter potential coil terminal "$\pm W$" permits using the same multipliers and terminals for the wattmeter potential circuit connection as are used for the voltmeter connection. The letters "A", "M", "V", and "W" refer to the terminals to be used for the ammeter, milliammeter, voltmeter, and wattmeter connections respectively. The larger terminals are for the current circuit and the smaller terminals for the potential circuit. Both pairs of terminals, "AM" and "A" are closed with links for the ammeter connection. For the milliammeter connection, only the terminals "AM" are closed, and all current coils are connected in series. The scale is calibrated for all four services.

Table III gives the full scale reading and the power consumption at this reading for each connection. The data are for the "1X" range of the ammeter, the voltmeter, and the wattmeter, and for the single range of the milliammeter.

Table III. Calibrated Ranges and Full Scale Power Consumption of Low-Frequency Indicating Instrument

Instrument Connection	Full Scale Range	Power Consumption
Ammeter	1.5 amperes	0.5 watts
Milliammeter	100 milliamperes	0.5 watts
Voltmeter	75 volts	1.4 watts
Wattmeter	75 watts	1.5 watts*

* For one ampere in the current coil connected for "1X" range and for the "1X" range of the potential circuit in use.

The instrument mechanism and all resistors and terminals are mounted on a 1/2-inch bakelite panel 8 by 11 inches. This in turn mounts upon a welded steel box 5 inches deep which serves both as magnetic shield and case. With the exception of an air chamber contained in the inspection cover above the upper pivot, the whole is filled with the insulating fluid. Neoprene gaskets prevent leaks between adjoining parts. About $1^1/_2$ gallons of fluid is required. This fluid surrounding all coils and resistors prevents significant inequalities in temperature of the parts, hence, the temperature compensation is more easily controlled. An 8-hour test at full scale voltage on the "4X" range (300 volts and 5.6 watts) showed that the temperature rise of the fluid was 3 degrees centigrade.

Future Considerations

The authors are currently considering other possibilities for low-frequency instrument design such as the thermal instrument having a very long time constant along the lines described by Lincoln[3], and the use of a high moment of inertia magnetically-suspended moving system.[2] They also are considering the problem of using vacuum-tube amplifiers with these instruments for measurements on low-power level servo systems, and demodulators for adapting these instruments to the measurement of error-modulated signals.

Figure 5. Connection diagram and circuit constants of low-frequency instrument shown in Figure 4

Conclusions

As a result of these investigations, it is concluded that:

1. Conventional instruments will perform accurately from direct current to approximately 0.01 cycle per second, and excepting the permanent magnet-moving coil instrument, above 1.0 cycle per second.

2. The electrodynamometer instrument damped to the slightly oscillatory condition gives the narrowest unreliable zone C.

3. When zone B operation can be sacrificed, and a long time constant can be tolerated, zone A operation can be extended by heavy damping of conventional instruments.

4. Increasing the moment of inertia and decreasing the spring constant is not feasible in conventional instruments.

5. An instrument expressly designed with a large natural period and proper damping affords the opportunity of bridging the zones where conventional instruments are unreliable.

Appendix I. Motional Equations of Instrument Movements

The equations of motion of the pointer can be derived from the following fundamental equation of motion

$$J\frac{d^2\theta}{dt^2}+D\frac{d\theta}{dt}+K\theta=\tau_e \tag{2}$$

where

J = moment of inertia
D = damping constant
K = spring constant
θ = instantaneous angle of deflection
τ_e = instantaneous electrical torque

The electrical torque developed by the various instruments when used to measure sinusoidal quantities is given by the following group of equations

Permanent magnet-moving coil

$$\tau_{eA}=K_A i_M=\sqrt{2}K_A I_M \sin(\omega t) \tag{3}$$

Electrodynamometer

$$\tau_{eD}=i_f i_M\frac{dM}{d\theta}=2I_f I_M\frac{dM}{d\theta}\sin(\omega t)\times\sin(\omega t+\phi) \tag{4}$$

Moving-iron

$$\tau_{eI}=K_I f(\theta)i_f^2=2K_I f(\theta)I_f^2\sin^2(\omega t) \tag{5}$$

Rectifier (full wave)

$$\tau_{eR}=K_A i_M=\frac{2\sqrt{2}K_A I_M}{\pi}\times\left[1+\sum_{q=1}^{n}\frac{-2}{4q^2-1}\cos(2q\omega t)\right] \tag{6}$$

where

i_m, I_m = instantaneous and effective value of the moving coil current
i_f, I_f = instantaneous and effective value of the fixed coil current
K_j = instrument constant of the jth instrument
$f(\theta)$ = function depending upon the deflection alone
ϕ = phase angle between the currents i_m and i_f
M = mutual inductance between the fixed and moving coils

It has been shown[1] that the a-c steady-state solution of equations 2 and 3 for the D'Arsonval instrument is (Graybeal's equation 6)

$$\frac{\Delta R}{R_{max}}=\frac{1}{\left[\left(\frac{2\omega}{\omega_n}\beta\right)^2+\left(1-\frac{\omega^2}{\omega_n^2}\right)^2\right]^{1/2}} \tag{7}$$

where ΔR is the maximum minus the minimum reading and R_{max} is the reading corresponding to the maximum value of the impressed electrical quantities. Thus the curves in Graybeal's paper apply to the performance of the D'Arsonval instrument under these conditions.

Solving equations 2 and 4 results in the a-c steady-state solution for the electrodynamometer instrument

$$\theta=I_f I_M\frac{dM}{d\theta}\left\{\frac{\cos\phi}{K}+\frac{1}{\sqrt{(K-4\omega^2J)^2+(2\omega D)^2}}\sin(2\omega t+\lambda)\right\} \tag{8}$$

From which the total change in deflection

$$\Delta\theta=\frac{2CI_f I_M}{K\sqrt{\left[2\frac{2\omega}{\omega_n}\beta\right]^2+\left[1-\left(\frac{2\omega}{\omega_n}\right)^2\right]^2}} \tag{9}$$

if $dM/d\theta$ is assumed to remain constant. Since the reading is proportional to the square root of the deflection, the per-unit change in reading can be written as

$$\frac{\Delta R}{R_{max}}=\frac{(\theta_{max}+\Delta\theta)^{1/2}-(\theta_{max}-\Delta\theta)^{1/2}}{\sqrt{2}\theta_{max}^{1/2}} \tag{10}$$

where $\Delta\theta$ is described by equation 9 and

$$\theta_{max}=\frac{2CI_f I_M}{K} \tag{11}$$

These equations were employed in obtaining the calculated results shown in Figure 1, for the electrodynamometer instrument.

The solution of the moving-iron equations results in an equation that is very similar to those for the electrodynamometer instrument except that some assumption regarding $f(\theta)$ must be made. The authors have found that the assumption that $f(\theta)$ is constant leads to fairly reliable results in this case. When this simplifying assumption is made, the calculations are very similar to the electrodynamometer case except that the actual curve of reading versus deflection must be used to obtain the ratio $\Delta R/R_{max}$.

The rectifier instrument solutions will appear to be very similar to equation 8 except that there will be an infinite series involved.

Appendix II. Mechanical Design Requirements of Low-Frequency Instrument

The experimental data exhibited in Figure 1 show that several conventional instruments are available for zone B operation up to approximately 0.07 cycle per second. This frequency, therefore, marks the lower boundary of zone A of a low-frequency instrument needed for use in zone C of these instruments. Based upon laboratory observations the lower end of zone A has been arbitrarily limited to a per unit change in reading of 0.05. For instruments having approximately a square-law scale, such as an electrodynamometer voltmeter, this change in reading corresponds very nearly to a per-unit change in deflection of 0.10.

From equations 9 and 11

$$\frac{\Delta\theta}{\theta_{max}}=\frac{1}{\sqrt{\left[2\frac{2f}{f_n}\beta\right]^2+\left[1-\left(\frac{2f}{f_n}\right)^2\right]^2}} \tag{12}$$

Solving this equation for f_n

$$f_n=f\sqrt{\frac{1}{1-2\beta^2\pm\sqrt{4\beta^2(\beta^2-1)+\left(\frac{\theta_{max}}{\Delta\theta}\right)^2}}} \tag{13}$$

Substituting $f=0.07$, $\Delta\theta/\theta_{max}=0.1$ and $\beta=1$, results in an undamped natural frequency of 0.047 cycle per second for the low-frequency instrument.

If the spring constant is specified, the required moment of inertia can be computed from equation 1. For a spring constant, K, of 0.18 gram-centimeters per radian, which was selected because of availability, the moment of inertia required is about 2,000 gram-centimeters squared. The foregoing steps give the procedure used in determining the basic mechanical requirements of the low frequency instrument.

The final mechanical design requirement remaining was to specify a shape and size for the moving system which would have the required moment of inertia and at the same time be largely supported by the insulating liquid. A readily available clear mineral oil and pearl oil, a combination frequently used in magnetic oscillograph galvanometers, was chosen to serve as the supporting fluid because these two could be combined to give a wide range in viscosity for adjusting the damping with very little change in density. Also from preliminary tests no detrimental effects of these liquids on the insulation and other materials in the instrument could be discovered.

Because of the ease of fabrication and of balancing, the shape chosen for the coil form of the moving system was that of a right circular cylinder. This resulted in a rectangular shape for the moving coil. To keep the electrical losses in this coil to a minimum, the decision was made to allocate as much of the weight as possible to the coil and to keep the ratio of the length of the coil (diameter of the cylinder) to the height of the coil (height of the cylinder) within a reasonable value. The initial estimates on the shape and size of the moving system were made by assuming the cylinder to be solid and to have an effective density the same as that of the fluid. For this system the moment of inertia is

$$J=(1/2)WR^2 \tag{14}$$

The weight, W, of the moving system is

$$W=\pi R^2Hd \tag{15}$$

where R is the radius, H is the height both in centimeters and d is the density of the cylinder. From these relationships and the required moment of inertia it follows that

$$HR^4 = \frac{5{,}000}{\pi} \tag{16}$$

It is seen that if a small R is chosen, the cylinder becomes extremely long and of considerable volume, and if a large R is chosen, the cylinder becomes very thin. Either of these results in a greatly elongated moving coil. An initial choice in which H was set equal to R was made; in this case 4.36 centimeters which gave a moving coil with length of 3.45 inches and height of 1.72 inches.

As more complete computations were made taking into account an estimate of the maximum weight of wire consistent with minimum safe cylinder thickness and the actual moment of inertia of this wire together with that of the remaining hollow cylinder, very few changes in the dimensions were deemed advisable. Figure 4 shows the final dimensions.

For construction purposes about 5 per cent more wire than actually needed was specified for the first model of the instrument. Most of this extra wire was subsequently removed a small amount at a time from each side of the moving coil in turn to obtain balance and proper weight of the moving system when submerged.

The Extension of Amplistat Performance by A-C Components

R. E. MORGAN
MEMBER AIEE

H. M. OGLE
ASSOCIATE AIEE

V. J. WATTENBERGER
NONMEMBER AIEE

APPLYING amplistats to exacting control problems often reveals that effects normally considered of a secondary nature determine the actual performance limits. By studying these effects, it is usually possible to design circuits which avoid these limitations. In some cases, by controlling the effect, it is possible to considerably extend the performance of certain control systems. Circuits for amplistats and other magnetic amplifier systems have been well covered in previous papers.[1-3] Most work in this field has been concerned with pure d-c signals and a true sine wave power supply. In practical amplifiers designed to give high gain, fast response, and stable operation, these conditions are rarely met. This paper will study some of the effects normally encountered and will suggest possible means to control these effects.

It has been shown that the firing angle of a self-saturated magnetic amplifier is controlled by the time integral of the voltage applied to a winding linking the core.[4,5] This is the case when any number of windings link the core and includes, therefore, both control and output windings (account must be taken, of course, of the number of turns of each of the windings and any appreciable voltage drop). Any variation in the wave shape of the power supply occurring before the firing point will, therefore, have the same effect upon the firing time as a corresponding variation in signal. Any variation in the wave shape of the power supply occurring after the firing point will not affect the firing time. Either of these possibilities will influence the average value of the output current, but variations occurring before the firing point will have their effect amplified by the action of the amplistat and are usually far more important. It is possible, then, to cause a large change in the output of an amplistat by varying the wave shape of the power supply. This can often be done with no change in the rms value of the power supply voltage.

A study of the effects of pulses of voltage applied to amplistat windings is, therefore, desirable to gain a more complete understanding of the proper methods of application.

Procedure

For simplification, let us consider an amplistat element connected in a circuit shown in Figure 1. (For an experimental setup, the amplistat consists of two such circuits, but only one need be instrumented.)

Let us first consider the operation of this circuit with a square wave a-c supply in order to more easily interpret the results. The output curve of this circuit element with a d-c signal would be as shown in Figure 2.

With no signal, the circuit operation is as illustrated by Figure 3.

The line voltage appears across the reactor (*a-b*) until saturation, after saturation the voltage drop across the reactor falls (*b-c*) and current flows and approximately full-line voltage appears across the load (*b-c-d*). The current flows continuously until the line voltage reverses (*d-e*) at which time the voltage across the reactor reverses due to the decay of flux. Current cannot flow in this direction due to the blocking action of the rectifier and the voltage drop disappears from across the reactor after the collapse of flux is complete and appears across the rectifier (*f-g*). Figure 4 illustrates the same conditions with a sine wave supply.

If we apply a negative d-c signal to the reactor, we can move along the hysteresis loop, Figure 5, until we reach a point at which the reactor no longer saturates. The signal may be increased until the entire supply voltage appears across the reactor. At this point where the output is a minimum, the reactor is operating about the points on the hysteresis loop designated as *d-e-f-g*, Figure 5.

Discussion

When the core is saturated, there is very little coupling between the signal winding and the load winding. When the core is unsaturated, however, nearly perfect transformer coupling exists between these circuits. This is illustrated by Figure 6 which shows a 400-cycle a-c signal applied to the test reactor with a 60-cycle square wave supply. When pulse signals are considered, it is convenient, therefore, to consider the circuit in terms of several different equivalent circuits as shown in Figure 7.

In Figure 7(A), a simplified equivalent circuit is given for the operation during part of the negative half cycle of the supply voltage (*f-g* in Figure 3). For positive signal pulses or small negative signal

Figure 2. Amplistat output characteristics

Figure 4. Amplistat wave shapes with no signal and with sine-wave supply

pulses, the circuit acts the same as a transformer with an open-circuited secondary winding. For large negative signal pulses, the circuit of Figure 7(B) must be used. If the induced voltage in the load winding is equal to or greater than the instantaneous value of the supply voltage, the rectifier will become conductive and further flux change in the core will be resisted by an induced current in the load circuit. The effects of large negative pulses occurring during this period is thereby limited.

That any effect at all occurs from pulses during this period can be explained by an examination of the hysteresis loop, Figure 5. The core will usually be at a point on the hysteresis loop slightly to the left of the vertical axis (point a) because of rectifier leakage and possible flux leakage. A current pulse will now take the core through a minor hysteresis loop and cause it to end at some different condition. For example, for a negative pulse a-b-c or for a positive pulse a'-b'-c', this will affect the time of firing (point b, Figure 3) of the next half cycle. It is to be noted that small negative pulses will, in general, have more effect than equal positive pulses because of the shapes of the minor hysteresis loops. It is worth reiterating that changing the amplitude of the negative pulse will have an effect only up to the point where the induced voltage in the load winding is equal to the instantaneous value of the supply voltage: voltage E, Figure 7(B).

Investigation has shown that the change in output current is a direct function of the length of the pulse in the half cycle preceding firing (f-g, Figure 3). This is due to the fact that the flux cannot change in the core instantaneously because of eddy currents. It takes a finite time to move to a new point on the hysteresis loop.

Negative pulses occurring during the period g-a, Figure 3, are in much the same category as those in the period f-g, except that the voltage E, in equivalent circuit Figure 7(B), is being reduced during this time. However, this is the region of possible maximum effect for a positive signal pulse, due to the fact that the core is moved to a region nearer saturation by the pulse (point b', Figure 5) and may not be allowed to complete its travel around the minor loop. This is due to the fact that supply voltage may reverse while the pulse is in effect, resulting in a change of the firing angle of the reactor.

After passing point a, Figure 3, the rectifier becomes conducting and the equivalent circuit of Figure 7(C) must be considered. From here until firing point b, any pulse in the signal winding current will be opposed by an induced current in the load circuit and will, therefore, have a greatly reduced effect. The amount of this reduction is obviously a function of the load impedance.

After firing, point c, Figure 3, the core is saturated and no coupling effect exists between windings and the signal current is no longer induced into the load winding. The equivalent circuit for this condition would be as shown in Figure 7(D), where the signal would be impressed upon an equivalent impedance.

Oscillograph records were taken of a reactor operating under these various conditions. For example, let us consider the reactor with a pulse signal of varying

Figure 3. Amplistat wave shapes with no signal and with square-wave supply

Figure 5. Hysteresis loop for core material showing approximate minor loops through which core material is driven by pulse signals

Figure 7. Equivalent circuits

polarity and phase. If we consider a pulse time which is short compared to the a-c supply, it is possible to illustrate the effects described.

Figure 8 illustrates a negative pulse signal at the point of maximum effect for a reactor with a sine wave supply. As expected, this occurs at the point of maximum instantaneous supply voltage in the half cycle preceding saturation because of the varying effect of rectifier leakage. If we utilize a square wave a-c supply as illustrated by Figure 9, we can determine that the pulse d-c signal will have the same effect at any time from f to g in the preceding half cycle. Figure 10 illustrates a positive signal at its point of maximum effect as explained previously. Summarizing, we find the following:

1. The effect of the pulse signal in the preceding half cycle during which the core is not saturated is to drive it around a minor hysteresis loop to a new position. The new position will be determined by the pulse height and by the length of the pulse for any core with appreciable eddy currents.

2. The induced voltage in the load winding, when the core is not saturated, is a function of the signal current times the turns ratio of the windings. It is limited, however, to a value slightly greater than the instantaneous value of the supply voltage.

If we extend our study to varying d-c pulse lengths and to sine wave a-c signals, it can be shown that these effects continue to apply. The factor that is important is that the final position on the hysteresis loop is determined by the summation of voltage time integrals applied during the previous half cycle. Figures 11 and 12 illustrate the appreciable change in output current which may be realized by a few degrees shift in phase between signal voltage and supply voltage.

The same analysis can be extended to include amplistats made up of several of the fundamental elements described.

Applications

The proper utilization of the effects described extends the efficiency of the amplistat in circuit operation. For example, amplistat voltage and frequency regulators have been built with flat or even negative regulation with loads of varying power factor. This is accomplished by using phase shift of ripple components for primary control and the additional use of wave shape changes for regulator droop compensation. By means of this compensation, the regulator is more stable because high-loop gain is not required.

Voltage Regulator

The voltage regulator consists of three main parts, as illustrated by the circuit, Figure 13:

1. Saturated transformer—voltage regulator element.
2. Phase shift network—compensator.
3. Amplistat—amplifier.

The characteristic of the regulator is based on the amplistat, recognizing the phase shift of ripple components; the wave shape change; and the d-c control current.

The regulation is obtained by use of the phase shift in the output of the saturated transformer. The regulation is improved by compensation taken from wave shape changes of the alternator and supplied through the bias. This was done by a phase shift network of C_1 and R_4 in the circuit, Figure 13.

Saturated Transformer

The output of the saturated transformer after saturation is constant when

Figure 6. Amplistat wave shapes transformer action with 400-cycle signal

measured by a meter. However, the output is an effective phase shift (leading) with an increase in applied voltage. This is illustrated by Figure 14 which shows that as the applied voltage is increased above the value required for saturation, the conducting time is decreased.

This output is rectified and applied unfiltered to an amplistat which is biased to the desired operating point. The circuit operation is such that an increase in alternator voltage gives a phase shift of amplistat signal current to a position of less effect. This gives a decrease in amplistat output and hence a decrease in alternator field current.

The circuit is such that the bias need not be a constant direct current, but can be derived from alternator voltage. Therefore, this bias also was used to supply alternator wave shape changes for droop compensation.

Droop Compensation

The small amount of wave shape change that occurs in most alternators can be shifted to the most sensitive phase and used as an ideal compensator which varies with load only. Although the distortion may be only 1 per cent, it is still very useful. The distortion usually changes from no load to full load. As load is applied, there are dips that occur in part of the alternator's voltage wave shape, while rises appear in other parts. The effective dips usually occur in one 90-degree section, while the effective rises usually occur in the other 90-degree section of each half cycle in the alternator voltage. In the oscillogram of Figure 15, the average of the dips occurred in the lagging 90 degrees, while the average of the rises occurred in the leading 90 degrees. Both the dips and rises could have been used by shifting the rises lagging and the dips leading. That is, shifting each into the most sensitive phase for an amplistat. However, the dips gave sufficient compensation for voltage regulation. So capacitor C_1, Figure 13, was used to shift the dips to the most sensitive phase for a positive signal in the amplistat.

Also, the phase shift caused by the wave shape change was used. This was an effective phase shift leading as load was increased which decreased the output of the 2-stage amplifier and the alternator field current. Thus an effective control was designed using change in both amplitude and phase shift of the alternator's output wave shape. With this particular circuit, it was possible to obtain a regulation of −0.5 per cent; however, this is seldom required so this circuit is used to obtain regulations of 1.5 per cent with

unity power factor load and 1.3 per cent with 80 per cent power factor load.

Frequency Regulator

The same amplistat characteristics have been used to design frequency regulators with flat characteristics. The technique is very similar to that used for the voltage regulators described previously.

The frequency regulator circuit consists of a resistor and capacitor network, and a 2-stage amplistat, Figure 16. The resistor and capacitor network has three functions: to give a signal that varies with frequency; to give a signal that varies with load only; and to give a phase shift so as to position phase of frequency signal; position phase of wave shape change compensation; and increase effective amplification of the amplistat.

As discussed previously, the output of any alternator has wave shape changes which occur as a function of load. This change is, effectively, the appearance of dips and rises at different phases of output voltage. In this particular circuit, the dips and rises were shifted to the most sensitive phase in the amplistat characteristic by a resistor-capacitor network.

The same network was used to form a frequency circuit. This was accomplished by circuit elements R_1, C_1, C_6, C_5, and R_5 of Figure 16 which supplied I_c. The result is that as the load was increased, the tendency of frequency to decrease caused I_c to decrease. Also, the dips increased, thus I_c was further decreased with a resultant decrease in the output of the 2-stage amplistat and motor field current.

The rises in the alternator wave shape, due to wave shape change, were shifted lagging and fed in as part of I_R. By shifting, the effect of I_R was made to increase as frequency decreased and load increased. Therefore, the total effect of I_R and I_c gave a push-pull signal from both frequency changes and load changes (wave shape changes). This also cancelled the influence of voltage changes in both circuits.

The frequency regulation was further improved by use of phase shift in both the frequency circuit and the compensator circuit. I_R was shifted leading by a decrease in frequency. The shift leading of I_R was in the same direction as the shift of the saturating phase in the first amplistat stage. Since the amplistat recognizes phase shift in its signals, the phase shift of I_R is in the direction to increase the effect of a frequency change.

In addition, the wave shape change of the alternator voltage produced a rise in the leading edge and a dip in the trailing edge, as load was increased. That is, effectively, a leading phase shift. Therefore, as the load increased, this shift in phase had a similar effect on the amplistat as a drop in frequency. As a result, the phase shift, as well as amplitude, in both the frequency circuit and the compensator circuit, was used to improve the regulation.

The signal I_c also was used to aid in the phase shift. This was accomplished by

Figure 13. Voltage regulator circuit

Figure 14. Saturating transformer characteristic

Figure 15. Alternator wave shape

Figure 16. (right) Frequency regulator circuit

shifting I_c slightly leading of the optimum phase for a negative signal. Therefore, as the frequency decreased, I_c shifted more leading. Thus, the effect of I_c decreased and caused the output of the first stage to increase further. Therefore, the above resulted in increasing the output of the first stage and decreasing the output of the second stage in the amplistat. That decreased the motor field sufficiently to hold speed as load increased. The inverse is true with an increase in frequency.

The amplistat is sensitive to both the magnitude and the phase of the ripple which appears in the signal. In this particular circuit, these factors have been used to an advantage by the proper selection of C_4, R_4 and C_4, R_4, to give additional gain.

If any of the foregoing factors are applied incorrectly, stabilizing problems may enter. In fact, if enough of them are applied incorrectly, it may be impossible to get good regulation under various load conditions.

Additional Circuit Problems

With multistage amplifiers, trouble is sometimes encountered because of the common power supply. As stated previously, the amplistat is sensitive to changes in either supply voltage or signal current during the time the core is being driven around a minor hysteresis loop. The power stage will frequently put a sharp dip in the power supply voltage during firing. This dip may adversely affect the input stage or stages.

One method of overcoming this limitation for sensitive amplifiers is to use a carefully controlled square wave as a power source. Such square waves may be obtained by clipping sine wave power supplies with either conventional clipping circuits or with circuits involving series-connected saturable core reactors. Permanent magnet biased saturable reactors have been successfully used in circuits of this type.

Conclusion

In addition to the control effect of d-c signals, amplistats can be controlled by a-c components. Anything which changes the condition of the core material prior to the start of build-up of load current can cause a large effect. During build-up of load current, and before saturation, a-c components in the signal can only produce a much smaller effect. After saturation, they can produce no effect. Therefore, the phase of a-c or pulse signals is of major importance.

In general, a negative signal will have its maximum effect in the half cycle preceding saturation at the point where the instantaneous value of supply voltage is greatest.

A positive signal has its maximum effect during the time of the supply voltage reversal which immediately precedes firing.

Ignitron Pulse Equipment for Particle Accelerators

C. C. HERSKIND
FELLOW AIEE

J. E. HUDSON
NONMEMBER AIEE

RECENT advances in atomic research have resulted in the development of various types of particle accelerators employing current pulses of short duration and high amplitude to produce intense magnetic fields. Ignitron tubes with mercury pool cathodes have been used as switching devices in the power circuit to apply such current pulses.

The choice of the ignitron tube is based on its ability to carry current pulses having crest values of 5 to 15 times sustained ratings. The use of the ignitron tube also permits accurate control of the time at which the current pulses occur. This is necessary in order that the magnetic field may be properly timed in relation to the other physical processes associated with the particle accelerator operation.

A very intense magnetic field providing high energy levels may be obtained with low continuous energy input and a substantial saving in equipment by exciting the magnet coils of the particle accelerators by pulses of current.

A number of applications have been made. One application employs a total of four sealed ignitrons of type *GL506* connected to operate in pairs with each pair carrying a crest pulse current of 5,300 amperes at 17 kv. The current pulse which is produced by the discharge of a capacitor bank through one pair of tubes is a half sine wave of 1/120-second duration. It is applied at a repetition rate of six pulses per second. The second pair of tubes is used to reverse the charge on the capacitor. The first equipment of this type was supplied to the University of California Radiation Laboratory for their 300 mega-electron volt synchrotron and similar equipments have been furnished to others.

A second application employs four pumped ignitrons of 16-inch diameter. These tanks deliver a crest pulse current of 30,000 amperes at 6 kv. The current pulse and repetition rate are the same as for the first application. The capacitor charge is reversed by switches. One equipment of this type has been installed by the University of Illinois for their pulsed betatron.

A third application consists of 12 type *GL506* sealed ignitrons with eight tubes connected in parallel to provide a magnet current of 28,000 amperes at 20 kv. The remaining four tubes reverse the capacitor charge through a separate reactor. The magnet current pulse is a half sine wave of 1/1,200-second duration. The equipment is designed to operate at repetition rates up to 60 pulses per second. In order to permit operation at high current levels, the tubes are provided with commutating reactors. This equipment will supply power to the 300 mega-electron volt nonferromagnetic synchrotron being built by the General Electric Company Research Laboratory under the sponsorship of the Office of Naval Research.

The purpose of this paper is to outline the operational principles and requirements of equipment for pulse service. The arrangement and features of the equipment are described. Data on ignitron performance in pulse operation is presented.

The Pulsing Action

A high current pulse of 0.01 second or less duration is desired for energizing the magnet coil of some types of particle accelerators. In order to minimize the load demand and maintain an essentially constant drain on the a-c power supply, a large capacitor bank is used to store energy for producing the current pulse. This capacitor is charged to a high direct voltage by means of a rectifier connected to the a-c power supply. At the desired time, the capacitor is connected in series with the magnet coil by means of an ignitron tube and the current discharge through the coil takes place.

A typical power circuit for producing current pulses is shown in Figure 1. The operation of the circuit is as follows: The capacitor bank is first charged to a fixed direct voltage by means of a high-voltage rectifier. The current drawn from this rectifier is limited by means of impedance elements such as a diode limiter and a d-c reactor. At the desired time the ignitron discharge tube is made conductive and the capacitor is permitted to discharge through the magnet coil. The subsequent circuit action is shown by current and voltage wave forms in Figure 2.

The magnitude and duration of current pulse are determined by the capacitor voltage and the impedance of the capaci-

Figure 2. Circuit wave forms and tube duty

tor and magnet coil. At the end of the current pulse in the discharge tube, the voltage of the capacitor is negative. In order to reverse the polarity of the capacitor and rechange it to its original voltage, the recharge tube is made conductive and the capacitor is discharged in the reverse direction. Since the resistance of the circuit is low and little energy is dissipated in the magnetic field, the capacitor voltage at the end of the second current pulse is but slightly less than its original value. The capacitor voltage is brought back to normal by the charging rectifier before the succeeding current pulse.

The recharge current flows through the magnet coil in the circuit shown in Figure 1. The capacitor voltage also may be reversed by recharging through a separate reactor or by providing means for reversing connections.

Figure 3. Electronic contactor assembly—view of ignitron tube and grid boxes taken from tube side

Current pulses of 5 to 30 kilo-amperes are required for some types of particle accelerators. To obtain currents of this magnitude by using available tubes and to limit the fault currents in the event of tube failure, the power circuit in actual installations usually consists of a number of parallel tubes or circuits. By providing anode reactors to insure current division, tubes may be operated in parallel to discharge a single capacitor bank. An alternative paralleling arrangement is obtained by dividing the capacitor banks into a number of sections corresponding to the number of tubes and totalizing tube currents in the magnet coil.

Description of Electronic Contactor

The part of the power circuit equipment which performs the switching function, that is, the electronic contactor, consists of the ignitron tubes with their excitation and temperature regulating equipment (also evacuating equipment when pumped ignitrons are used). The excitation equipment, which is assembled in a grid box, and the ignitron tubes are mounted on a common frame which is usually insulated from ground. Insulating power and signal transformers are, therefore, required for energizing the excitation circuit and controlling tube firing. Insulating hose or pipe is likewise required for carrying cooling water to the tubes as the temperature regulating equipment is usually mounted at ground potential.

The general appearance of the tube and grid box assembly is shown in the figures. Figure 3 shows an assembly of two tubes with grid boxes viewed from the tube side of the equipment. Figure 4 shows an assembly of eight tubes viewed from the grid box side. The draw-out type construction is used for the grid boxes as this provides a compact assembly which is readily accessible for servicing. Figure 5 shows a grid box in the draw-out position with a portion of the excitation circuit exposed to view.

Ignitron Tubes

Two types of ignitron tubes have been used for these applications. One of these is the sealed ignitron *GL506* having a nominal inside diameter of 8 inches. A sectional view of this tube is shown in Figure 6. For rectifier operation this tube has a continuous rating for industrial service of 150 amperes average (450-ampere crest) at 20-kv peak inverse. This tube is fitted with three grids.

Figure 4. Electronic contactor assembly—view of ignitron tubes and grid boxes taken from grid box side

The other ignitron which has been used is of the pumped type shown in Figure 7. It has an inside diameter of 16 inches and is fitted with two grids. For rectifier operation this tank has a continuous rating for railway service of 200 amperes average (600-ampere crest) at 7,500-volts peak inverse.

Excitation Equipment

The excitation equipment is an essential and major part of the electronic contactor. Its functions are to establish the conditions for conduction in the power ignitron and to control the start of conduction. In greater detail, the excitation circuit must provide means for obtaining the following action:

1. Initiate a cathode spot on the mercury pool. The cathode spot may be produced by passing a suitable pulse of current through the ignitor.
2. Maintain the cathode spot and spread

Figure 5. Electronic contactor grid box—view of grid box in draw-out position with excitation panel partly exposed

ionization. Since the ignitor current pulse is usually of short duration, means must be provided for maintaining the cathode spot after the ignitor has ceased firing. The necessary holding current is obtained by means of the excitation anode.

3. Start conduction of the main anode. Conduction of the main anode may be started by applying a positive voltage to the grid of the ignitron tube.

4. Prevent conduction without cathode excitation. Means should be provided for holding the ignitron grid negative until after a cathode spot has been established on the mercury pool. If this is not done, the anode voltage may produce a spot on the tube side wall. Such a spot causes faulty operation and deterioration of the ignitron tube as a result of gassing and erosion of the metal surface.

5. Clean up ionization and regain control. Following the end of anode conduction, a negative voltage must be applied to the ignitron grids to hasten the clean up of ionization and regain grid control. This function must be completed before the main anode goes positive.

In particle accelerator operation, the timing of the current pulse in the magnet coil is determined by other physical processes which cannot be accurately synchronized with the power system. The power ignitrons must fire in response to an external signal which is nonsynchronous with respect to the a-c power system. An accurate time relation is required between the signal and ignitron firing. These requirements rule out the magnetic firing circuit commonly used with ignitrons in

rectifier service and necessitate use of excitation circuits employing vacuum tubes.

Two excitation circuits for use with electronic contactors have been developed. While they are quite similar and operate on the same principles one is designed for operation at repetition rates of 5 to 10 pulses per second while the other will operate at repetition rates up to supply line frequency. The choice of circuit depends upon the application requirements. While the second circuit possesses definite advantages over the first in that it provides for higher frequency operation and greater accuracy of firing, these advantage are obtained at the expense of increased number of firing tubes, complexity, and cost.

A schematic diagram of ignitron excitation circuit number 1 is shown on Figure 8 and the wave forms and firing sequence of the various electrodes on Figure 9. In this circuit, firing is initiated by an external signal which trips the ignitor firing tube. A current pulse produced by an inductance and capacitance discharge then flows in the ignitor. As soon as a cathode spot has been established by the ignitor, the excitation anode fires. Its current pulse also is produced by an inductance and capacitance discharge. Current flow in the excitation anode trips the grid firing tube through the permissive transformer. The grid firing tube applies a positive voltage to ignitron grid and ignitron tube becomes conductive.

All timing is determined by the one signal which trips the ignitor firing tube. The time at which the ignitron tube starts current conduction will be subject to a small jitter since the grid firing time depends upon that of the ignitor. In the

Figure 8 (above). Excitation circuit number 1

Figure 9 (right). Wave form and firing sequence in excitation circuit number 1

present design, the ignitor firing voltage and current have been selected to limit the ignitor jitter to 200 microseconds.

This excitation circuit permits parallel operation of two tubes. This is accomplished by providing the two tubes with individual ignitor and excitation anode circuits and using a common grid firing tube to energize the grids of both ignitron tubes. By connecting the output windings of the permissive transformers in series so that the sum of their voltages is required to trip the grid firing tube, the firing of both ignitron tubes is permitted only when cathode excitation has been established in each. Anode current division during conduction may be insured by the use of anode reactors.

The second excitation circuit is shown in Figure 10. It is designed to operate at repetition rates up to 60 pulses per second and provides accurate firing free from ignitor jitter. Wave forms describing the circuit action are shown in Figure

Figure 10. Excitation circuit number 2

Figure 11 (left). Wave forms in excitation circuit number 2

Figure 12. Pulse data on *GL506* sealed Ignitron

11. The action is similar to that of the first circuit. However, firing is initiated by two separate voltage impulses from the signal circuit. The first of these is positive and trips the ignitor firing tube thus firing the ignitor and excitation anode in turn. The second impulse is negative and follows the first by a short time interval to allow sufficient time for the ignitor to fire. The grid firing tube, which is tripped by the second impulse, discharges an artificial transmission line to produce a square voltage pulse. This pulse is of sufficient amplitude to overcome the fixed negative grid bias and fire the grid of the ignitron.

Both firing signals are transmitted to the grid box through the same signal insulating transformer. The ignitor and grid signals are of opposite polarity and are separated by the triode amplifier tubes connected to the center tapped signal transformer. A permissive circuit is provided by putting a second excitation anode in the signal amplifier tube circuit.

Temperature Regulating Equipment

The temperature regulating equipment consists essentially of a heat exchanger, a circulating water pump, a thermostatically-controlled regulating valve and a surge tank. The regulating valve automatically maintains a constant temperature on the water entering the tubes by regulating the flow of raw cooling water to the heat exchanger. The water pump is mounted in the surge tank together with immersion heaters for bringing the tubes up to operating temperature.

On installations where the tubes are mounted at high potential and the temperature regulating equipment is mounted at ground potential, insulation between tubes and heat exchanger is obtained by lengths of rubber hose or porcelain water coils. Pure water of high resistivity is used in the recirculating system. Electrolytic rods are provided to prevent corrosion of piping system by electrolysis.

Tube Performance

Tests and observations on ignitron tubes operated at high pulse currents show that the arc-drop rises and cathode spots form on the tube walls. The increased arc-drop may cause severe local heating. The cathode spots cause gassing and erosion of the metal walls, contaminating the tube and causing ignitor wetting.

In rectifier service, the usual criterion of tube performance is the arc-back rate. Experience has shown that life is generally satisfactory if the arc-back rate is kept low.

When ignitron tubes are operated at high pulse currents, the arc-back rate may be kept at an acceptable value by pulsing at a low repetition rate and providing commutating reactors. However, tube life may be seriously shortened by the contamination and heating effects mentioned previously.

Data regarding the current capacity, performance and life of ignitron tubes, and tanks in pulse service is somewhat limited. Because of the difficulty and cost of making adequate tests, it has not been possible to establish accurately the current level at which undesirable arc conditions arise, and effect of such conditions upon tube performance and life.

The results of experience obtained on the *GL506* sealed ignitron in field operation and factory tests are shown in Figure 12. This figure shows the currents which have been successfully carried without excessive arc-back. The following conclusions are indicated by the data:

1. The current capacity of the tube in single pulse operation with half sine wave (180 degrees) pulses at 60 cycles is approximately ten times its continuous capacity in rectifier service.

2. The crest current carried by the tube may be further increased by using commutating reactors and shortening the current pulse to provide current dragout at the end of conduction before application of the inverse voltage.

Summary

The power ignitron has been successfully applied in pulse service. This service imposes new operating conditions and has required the development of new excitation circuits.

Crossbar Tandem System

R. E. COLLIS
MEMBER AIEE

LOCAL telephone traffic in a small community having fewer than 10,000 subscribers' stations can be adequately handled by a single telephone central office. When the number of stations increases beyond 10,000, it is necessary to establish a second office, the equipment for which may or may not be in the same building as that of the first office. In order to complete calls from a subscriber in one office to a subscriber in the other office, so called "direct trunks" are run between the two offices, the number of these trunks depending upon the amount of traffic. As the number of local offices and the distances between them increase, it may be found more economical to provide trunks from each local office to a common point or tandem office, than to run separate groups of trunks between each pair of local offices. Connections between the trunks from the various offices are then established at the tandem point as required.

Traffic between local manual offices through a manual tandem office is completed by the local or "A" operator passing the desired office name orally over a "tandem trunk" to a tandem operator at the tandem office. The tandem operator then tests for an idle trunk in the group of trunks to the required office and by means of a "cord" circuit connects the incoming trunk to the selected idle outgoing trunk. The local "A" operator then passes the called subscriber's number to a "B" operator at the called office who completes the connection to the desired line. It may be noted here that the "A" operator, the tandem operator and the "B" operator must be able to understand each other, that is, must speak a common language; if not it would be necessary for the tandem operator to act as an interpreter or translator between the "A" and "B" operators. Furthermore, the tandem operator must perform the job of selecting the proper outgoing trunk group and also that of selecting which particular trunk she will use to complete the connection.

As manual local operation was replaced by dial operation, it became desirable to replace the manual type of tandem operation by automatic operation. Automatic installations in many of the small offices were of the step-by-step type and it was logical that the automatic tandem equipment for these areas should be of this type. Since in this case it is necessary to deal with only one type of language, namely, decimal pulsing, the tandem switches and the switches beyond the tandem are operated directly by the pulses coming over the trunk. The step-by-step tandem cannot, therefore, act as an interpreter or translator where it is necessary to operate the terminating equipment on some other than the decimal type of pulsing.

In most of the larger cities of the country, the local automatic equipment was of the panel type, and later of the Number 1 crossbar type. Two tandem systems known as office selector tandem (or 2-wire office tandem), and panel sender tandem were developed for these areas. Like the step-by-step tandem, the office selector tandem can operate on only one language, namely, "revertive", and cannot act as an interpreter or translator. In the revertive type of pulsing, the selectors at the terminating office signal the successive steps in their advancement by momentarily short circuiting the tip and ring conductors. The panel sender tandem is more versatile than either the step-by-step tandem or the office selector tandem in that it can translate the incoming information into the revertive, call indicator, step-by-step and call announcer languages. However, it is arranged to receive only one language, namely, panel call indicator which consists of a series of tip and ring reversals in a coded sequence.

As the mechanization of local offices continued at a rapid rate, the need became imperative for an automatic tandem system which would combine such features as:

1. Ability to receive all the various types of pulse languages.
2. Ability to translate any of these languages into any of the others.
3. Adequate trunk capacity.
4. Greater trunking flexibility both as to assignment of the trunks on the trunk switches and as to the number of trunks in the trunk groups, than the existing systems.
5. Ability to complete through any of the other tandem systems.
6. Arrangements for concentration of certain traffic such as time announcements, weather reports, and so forth.
7. High-speed operation.
8. Inherent flexibility to permit the incorporation of new features to meet new conditions as they arise.

With these objectives in mind, the development of the crossbar tandem system was undertaken in the late 1930's. The first phase of this development was completed and a few offices installed before the war. Since the war, continuous development has been in progress and many new features have been added.

This paper describes the crossbar tandem system and how the incorporation of the foregoing basic requirements is enabling the system to fill an ever-expanding field in the mechanization of the Bell Telephone System.

General

Many of the circuit and equipment arrangements of the crossbar tandem system are similar to those of the Number 1 local crossbar system which was introduced by the Bell System in the late

Paper 50-158, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 14, 1950; made available for printing April 18, 1950.

R. E. Collis is with the Bell Telephone Laboratories, Inc., New York, N. Y.

Figure 1. Crossbar switch—front view

1930's and described in detail by F. J. Scudder and J. N. Reynolds in a paper presented to the Institute in January 1939.[1]

Like the Number 1 crossbar system, the basic switching unit is the crossbar switch, Figure 1. Other apparatus employed consists almost entirely of multicontact relays and small relays similar to those employed in other crossbar telephone systems.

In order to perform its job as an intermediary between all varieties of originating and terminating offices, a number of types of senders are provided, each able to receive a different language from the originating point. With the help of a "marker" each sender is able to translate the incoming information into the language required to reach the terminating point.

The major switching operations are controlled by large common circuits or "markers." A marker is used only once per call and it performs its functions so quickly that only a few are required, even in large offices.

As in the Number 1 crossbar system, the markers are arranged to detect short circuits, open circuits, false grounds and other troubles and to check that the connection is properly established before it releases. If trouble is encountered the nature of the trouble is indicated on a trouble indicator and a second trial is made, a feature which is possible only in common control systems.

Types of Office Interconnections

Figure 2 shows the various types of originating and terminating offices which can be interconnected through the crossbar tandem system. As indicated in the figure a separate sender is provided for each type of language which must be received, namely; revertive, dial, or multifrequency pulsing. All senders are arranged with the help of the marker to translate the incoming language into the proper language required by the terminating office.

In panel offices the subscriber dials the code and number into a sender in his local office or the operator at the *DSA* board keys the number on a d-c key pulsing basis into an operator's sender. In either case the sender at the panel office sends the selections, normally used for controlling panel selectors, into the revertive sender at the tandem office. These selections are used by the tandem equipment to set up the connection to the terminating office as explained later.

Operators' dial circuits at either local or toll dial switchboards are connected over the trunk to a dial sender at the crossbar tandem and the operator dials directly into the tandem sender. Certain types of switchboards equipped with d-c key pulsing, first connect to key pulsing senders which receive the keyed number and then automatically out-dial this number over the trunk into the tandem sender.

In step-by-step offices arranged for automatic ticketing,[2] the called code and number are first registered in a ticketing sender in the step-by-step local office. This sender then is connected over the trunk to the dial sender at the tandem office, after which the digits are dialed

Figure 2. Type of incoming and outgoing trunks which can be interconnected through the crossbar tandem system

automatically by the ticketing sender into the tandem sender.

In some areas advantage is taken of the crossbar tandem to permit step-by-step subscribers to dial panel, Number 1 crossbar and manual offices on a "second dial tone" basis. The subscriber in the step-by-step office after receiving the initial dial tone in the usual manner, dials a single digit which connects his line through the step-by-step switches in the central office over a trunk to a crossbar tandem office. When the tandem sender is ready to receive pulsing it returns a second dial tone to the subscriber who then proceeds to dial the wanted code and number directly into the tandem sender.

Incoming multifrequency pulsing[3] has only recently been introduced into crossbar tandem. This type of pulsing was first used in the Number 1 crossbar sys-system in 1941 and in the Number 4 toll crossbar system[4] in 1943. Switchboards that are equipped with multifrequency key sets are able to key over long toll lines directly into the multifrequency sender. This method of operation is being rapidly expanded in connection with toll terminating traffic since it enables toll operators in distant cities to complete calls without the assistance of operators at the terminating end. Number 5 crossbar offices[5] also may complete through crossbar tandem by the use of multifrequency pulsing.

As indicated in Figure 2, outgoing connections can be completed to all terminations requiring revertive pulsing, call indicator pulsing, and dial pulsing. Completion to manual straightforward positions, service and operator trunks also are provided. Development work now is under way to provide completion on a multifrequency basis as shown dotted in the figure. Further description of outpulsing features is given later.

Apparatus

Crossbar Switch

Since the crossbar switch was described in detail by Scudder and Reynolds,[1] only a brief review of its salient features will be given here.

Figure 1 shows a front view of a 200-point switch. Fundamentally the switch consists of:

1. Twenty separate sets of vertical paths each equipped with a holding magnet.
2. Ten separate sets of horizontal paths each equipped with a selecting magnet.
3. Five selecting bars each capable of assuming two selecting positions.
4. A mechanical means of connecting any one of the ten horizontal sets of circuit paths to any one of the 20 vertical sets of circuit paths by the operation of the corresponding selecting and holding magnets.

Figure 3. Block diagram of switching units

Any one of the 200 sets of contacts, called "crosspoints," can thus be closed by co-ordinate operation of a selecting magnet and a holding magnet. The contacts are held operated by the holding magnet alone, the selecting magnet being released as soon as the holding magnet is operated. A total of ten connections, one for each set of horizontal paths, can thus be simultaneously established. Each of the crosspoints may consist of from three to six separate "make" contacts, the number depending on the requirements of the circuit.

The switch shown is a 200-crosspoint switch, each crosspoint having three make contacts. This is known as a 200-point 3-wire switch. Other switches having only 100 crosspoints, that is ten vertical units, also are used in this system.

Relays

Multicontact relays having 30, 40, 50, or 60 sets of individually insulated make contacts, the same as in the Number 1 crossbar system are used in the tandem system. These relays are used chiefly in the common connector circuits where a large number of leads must be connected simultaneously.

General purpose relays of the (U) and (Y) type are used throughout the system. These relays may have as many as 24 springs arranged in various combinations of makes, breaks, and transfers. (U) and (Y) type relays are similar in physical construction except the (Y) type are provided with copper or aluminum sleeves and larger pole faces to secure slow operating and releasing characteristics.

A small number of other types of relays such as polar relays are required for special purposes.

Functions of Equipment Units

The general operation of the system may be more easily understood by first describing the principal equipment units and their functions. Figure 3 is a simplified block diagram which shows these units and their interconnection. In general there are six types of equipment units:

1. Tandem trunks.
2. Incoming and outgoing trunk link frames.
3. Senders.
4. Markers.
5. Sender link and controller frames.
6. Connector frames.

A tandem incoming trunk circuit consists of a few small relays, a repeat coil, capacitors, and resistances. These circuits provide supervisory and transmission facilities. An outgoing trunk usually consists only of three conductors, that is, tip and ring which go to the called office and the sleeve which is used for control purposes.

The incoming and outgoing trunk link frames which consist almost entirely of crossbar switches, provide means for connecting the incoming trunks to the outgoing trunks.

The senders consist principally of small relays. They register the called office codes and numbers which are pulsed from the originating offices and transmit the necessary information to the markers and to the terminating offices for completing the connections to the called lines.

The markers are the largest and most important of the common control circuits. They are composed of both small and multicontact relays. From the code of the called office, which is received from the sender, the markers determine the proper trunk group to the called office. They test the trunk group to find an idle trunk and also test to find an idle path or "channel" through the switch frames, after which they operate the proper selecting and holding magnets on the

Figure 4. Simple trunking arrangement with single 200-point crossbar switch

crossbar switches to establish the connection from the incoming to the outgoing trunk. The markers also furnish the senders with detailed information such as type of out pulsing and so forth, required to complete the call to the called office.

The sender link and controller frames provide means of connecting the incoming trunks to the senders. The operation of selecting the proper type of sender and connecting it to the trunk is performed by the sender link controller. A sender link frame is required for each 100 incoming trunks.

The marker connector, the trunk link connector, and the office link connector consist mainly of multicontact relays which are used for connecting the markers to the senders and to the link frames. These connectors operate on a lockout basis, that is, only one marker, for example, can connect to an office frame at one time through office link connector.

Trunking Arrangements

The fundamental method of using the switch in a trunking scheme is shown in Figure 4. Each of the horizontal and vertical lines represents the wires, for example, tip, ring and sleeve, of the connecting circuit. When the Number 0 selecting magnet is operated followed by the Number 0 holding magnet the tip, ring and sleeve leads of the circuit on the Number 0 horizontal are connected to the corresponding leads on the Number 0 vertical circuit as shown by the "X."

To obtain the required trunking access, 20 switches are mounted on a frame and interconnected in a primary, secondary arrangement as shown in Figure 5. Two types of trunking frames are used:

1. An incoming trunk link frame called a "trunk frame."

2. An outgoing trunk link frame called an "office frame."

Incoming trunks are connected to the horizontals of the primary switches of the trunk frames and outgoing trunks are connected to the horizontals of the secondaries of the office frames. The system is arranged for a maximum of 20 each of trunk frames and office frames which will accommodate a total of 3,200 incoming trunks and 4,000 outgoing trunks as explained later. Figure 6 shows an incoming trunk frame with associated incoming (or tandem) trunks.

The horizontal circuits on the secondary switches of the trunk frames and on the primary switches of the office frames are separated between the tenth and eleventh verticals, thus providing 20 horizontal circuits per switch instead of ten. These 200 horizontal circuits on the secondary switches of the trunk frame connect, as shown in Figure 5, to the 200 vertical circuits on the primary switches and are called "trunk links." Similarly, the 200 horizontal circuits on the primary switches of the office frame connect to the 200 verticals on the secondary switches and are called "office links." The circuits connecting the trunk frames and office frames are called "junctors." It will be observed that the total number of junctors from a trunk frame is 200. Since each trunk frame must reach each office frame the number of junctors which can be assigned between any two frames will vary depending upon the number of frames in the office.

Normally the horizontals on the secondary switches of the office frame are not divided. In this case only 100 trunks per frame can be accommodated. However, if the traffic density permits, these horizontals may be divided between the tenth and eleventh verticals to provide for additional trunk capacity. Also, if traffic density permits, ten extension secondary switches for the office frame may be provided. These switches have capacity for an additional 100 trunks per office frame. The horizontals of the extension switch are not arranged to be divided. The office links are multipled directly to the verticals of the extension switch as shown. The primary switches of the trunk frames are 200-point 6-wire switches. A special wiring arrangement of these switches permits 16 incoming trunks to be wired to the horizontals, that is, a total of 160 trunks per frame as shown in Figure 7. Each trunk is multipled as indicated to corresponding contacts on all 20 verticals of the switch. Since each horizontal consists of six springs, two incoming trunks of three leads each, that is, the tip, ring and sleeve, can be connected to each horizontal. Only the top eight horizontals are wired to trunks in this fashion, the odd numbered trunks being wired to the right-hand sets of three contacts and the even numbered trunks being wired to the left-hand sets of three contacts as illustrated. If the call originates on an odd-numbered trunk all six of the contacts at that horizontal crosspoint are closed, but only the right-hand set of three contacts is connected to the link. This is accomplished by closing the contacts associated with the Number 1 horizontal, simultaneously with the trunk horizontal contacts. If the call originates on an even-numbered trunk it is connected to the link by the use of Number 0 horizontal contacts. In this way any one of the trunks connected to the horizontals, two to nine, can be connected to any one of the 20 trunk links.

To establish a circuit from an incoming trunk to an outgoing trunk it is necessary to match three idle paths, namely a link on the trunk frame, a link on the office frame and a junctor between the two frames. The proper selecting and holding magnets must then be operated. These functions are performed by the marker as will be described later.

Description of Circuit Operation

The functioning of the system in establishing a connection may be divided into four major stages. These stages are:

1. Operation of the sender link and control circuit in selecting an idle sender of the proper type and connecting the selected sender to the tandem trunk.

2. Receiving and registering the called office code and number in the sender.

3. Operation of the marker in establishing the connection through switches and of furnishing the sender with directions as to how to complete the call.

4. Operation of the sender in transmitting information of the proper type to the called office.

Figure 5. Trunking plan

Although the foregoing is the normal progress of the functioning of the circuits, the operation of the senders can best be described by combining (2) and (4) and treating each sender separately. The operation of the marker will be considered last.

The first major stage is illustrated in Figure 8. When a tandem trunk is selected by the originating office, the sender link control circuit is brought into action. The sender link is a primary—secondary arrangement of crossbar switches. Each incoming tandem trunk is connected to a horizontal on each of two primary switches in order to insure completion of a connection to a sender if one linkage is in trouble. If the trunks are all of one type, 40 senders maximum of the corresponding type are wired to the horizontals of the secondary switches. If the trunks are of two types, two corresponding types of senders (maximum 40 of each) are connected to the secondary switches by dividing the horizontals of the secondary switches.

The control circuit proceeds as follows to connect a trunk to a sender:

1. Locates the horizontal position of the trunk on the primary switch of the sender link frame.

2. Selects an idle sender of the type required by the trunk. If the incoming trunk is of the revertive type, for example, the control circuit will test for an idle sender only in the revertive group of senders.

3. Selects an idle link between the primary and secondary switch.

4. Operates the proper selecting and holding magnets associated with the selected circuits, which establishes the connection from the trunk to the sender.

5. Signals the sender the number of the trunk frame with which the trunk is associated. This frame identification is used later in establishing the connection to the outgoing trunk.

6. Signals the sender the "trunk group" number to which the trunk belongs. All ten trunks appearing on the ten horizontals of a particular primary switch of the sender link frame are treated as a group. Since there are 100 trunks on the sender link frame, there are ten such trunk groups. All ten trunks of a group must be of the same type.

7. The control circuit then releases after checking that the connection between the trunk and the sender has been properly established. If trouble is detected an alternate control circuit is summoned which makes a second attempt to establish the connection.

As soon as the sender link control circuit has finished its functions, which takes but a fraction of a second, the tandem sender signals the originating office that it is ready to receive the pulsing of the called code and number.

The second and fourth major stages in the progress of a call are handled by the senders.

Revertive Pulse Receiving Sender

The revertive sender receives the office brush, office group, incoming brush, incoming group, final brush, final tens, and final units selections, revertively, from the originating sender in the panel or Number 1 crossbar offices and registers these selections on a crossbar switch. The office brush and office group selections represent the code of the terminating office, while the rest of the selections represent the number of the called line. Although there are normally only five office brush selections for panel operation, this number has been increased to ten for crossbar tandem operation by minor changes in the senders of the originating offices. The ten office brush and ten office group selections give 100 combinations or codes which can be transmitted over a single trunk group. By arranging the originating office to reach the tandem office over three separate trunk groups, a total of 300 codes can be recognized. Thus a particular combination of office brush and group selections, for example 37, may be used three times once in connection with each trunk group to represent three terminating codes. The sender link control circuit passes the trunk group number to the sender at the time that it is connecting the trunk to the sender.

The progress of sender operation is as follows:

1. Registers the office brush and group selections.

2. Opens the trunk toward the originating office. This is necessary because further selections after office brush and group must be delayed until the marker has informed the sender what type of outpulsing is required. If the call is to a manual call indicator position, the next trunk closure must

Figure 6 (left). Tandem incoming trunks and incoming trunk frames

Figure 7 (right). Wiring of crossbar switch for 16 trunks

come from the terminating office as explained later.

3. Connects to a marker by means of a marker connector and passes the office brush and group selections together with the trunk group and trunk link frame numbers to the marker.

4. Waits for the marker to set up the connection to the outgoing trunk.

5. Receives from the marker information as to the type of outpulsing and other information required to complete the call.

6. Releases the marker.

7. On other than call indicator calls, the sender closes the trunk toward the originating office and proceeds to register the incoming brush, incoming group, final brush, final tens, and final units selections sent out on a revertive basis from the originating panel and Number 1 crossbar offices.

8. If the terminating office requires revertive pulsing, the sender closes the trunk toward the terminating office and sends out the incoming brush, incoming group, and so forth, selections as they have been received from the originating office.

9. If the terminating office is of the step-by-step type, the sender translates the incoming and final selections back into thousands, hundreds, tens, and units digits of the called number and proceeds to dial these digits into the step-by-step terminating office. If the marker has so indicated, the sender dials out either one or two arbitrary digits ahead of the numericals. These digits are set up in the sender by the marker and provide switching features which are specially important in step-by-step areas. For example, these digits can be used to steer the call through step-by-step tandem switches or to cause the insertion of repeaters if transmission so requires.

10. If the terminating office requires call indicator pulsing the sender connects the incoming tip and ring leads to the outgoing tip and ring leads with a polar relay in the circuit When the call is assigned by the call indicator operator, the call indicator pulsing is done from the originating sender, the crossbar tandem sender being signaled when the pulsing is complete by the operation of the polar relay.

11. After the completion of outpulsing the sender operates relays in the tandem trunk which set the trunk in talking and supervisory position. The sender then releases from the connection.

Incoming Dial Pulse Receiving Sender

As in the case of the revertive sender, the dial pulse sender registers the incoming digits on a crossbar switch. This sender may be arranged for 2-digit codes, 3-digit codes or combined 2-3 digit codes, depending on the area in which it is used.

This sender is arranged to send out the numerical digits either on a call indicator, revertive or dial pulsing basis. The dial pulses are sent out as received. For revertive outpulsing, the incoming thousands, hundreds, tens, and units digits are translated into incoming brush, incoming group, final brush, final tens, and final units selections. For call indicator pulsing these digits are translated into the call indicator code.

The progress of the call through the dial sender is similar to that of the revertive sender except that the reception of the numerical digits proceeds without waiting for marker completion.

Multifrequency Receiving Sender

The multifrequency sender registers the incoming digits on relays instead of a crossbar switch. Associated with each sender is a multifrequency receiver which receives the multifrequency pulses and changes them into direct current pulses in order to operate the register relays. Five register relays per digit are required. These are operated on a 2-out-of-5 basis to register the ten decimal digits. The multifrequency sender is arranged to send out revertive, step-by-step and call indicator types of pulsing the same as the incoming dial sender.

The progress of the call through the multifrequency sender is similar to that of the dial sender.

Other Sender Features

Both the incoming dial and incoming multifrequency senders are arranged to receive ten "trunk group" signals from the sender link. This class signal is passed to the marker and enables the marker to determine the route and the charge for the call, depending on the class of the originating subscriber.

Both the incoming dial and incoming multifrequency senders are arranged to handle 3-digit service codes as well as "TX" operator codes of the "11X" type. A "TX" code is a special code used in connection with a delayed toll call to reach a

Figure 8. Trunk, sender, marker, and trunk frame interconnections

particular operator who has specific information as to the completion of the call. The two "1's" first dialed enable the sender to identify this type of call. "TX" codes may be of the type "11XX", or "11XXX" where the X's are any of the digits 1 to 0. Two X's are used when the number of operators is from 10 to 100 and three when the number is over 100 as is true in large cities. The senders will be arranged in a particular office for only one of these types of operation.

Marker

The tandem marker is basically the same as the originating marker of the Number 1 system. It is the most important of the common control circuits. Since calls coming into the revertive sender are on a 2-digit basis (plus the trunk group signal) the tandem marker is equipped with a 300-point translator operating in accordance with this information. The dial and multifrequency senders may be on a 2-digit only, 3-digit only, or a combined 2-3 digit basis and therefore the marker is equipped with a translator which will meet these conditions. The marker also has a translator for 90 service codes and 100, or 300 "TX" operators' codes. In addition to the code information, the marker receives from the sender the trunk link frame number and the trunk group number. From this information the marker sets up one of the several translators which results in the selecting of a code point, 1 of 300, 1 of 800, or 1 of 90 depending on which translator is involved. The selection of a code point operates a "route" relay which furnishes all further information required by the marker and the sender for completing the connection through the tandem office. There are a number of route relays in each marker since one is required for each called office route.

A route relay has 12 make contacts each of which controls a certain item of information required either by the marker or sender for setting up the connection. Upon the operation of the route relay the marker proceeds as follows:

1. Connects to the office frame on which the trunks to the called office appear. The marker places battery on a "start" lead to the desired office frame which operates relays individual to the marker on the office link connector circuit. The operation of these relays automatically locks out other markers from that office frame.

2. The marker connects a test relay to the sleeve lead of each of the trunks to the desired office and selects one of the idle trunks as indicated by these test relays. If all trunks tested are busy, a group of overflow trunks will be tested and the connection set up to an idle overflow trunk. If there are more trunks to the desired office than the marker can test simultaneously (40 the maximum) the marker is directed to a second group by a "route advance" feature.

3. The marker also connects by means of a trunk link connector to the trunk link frame on which the incoming trunk appears. The number of this frame was furnished to the marker by the sender. As in the case of the office link connector, only one marker can connect to a trunk frame at a time. The marker determines from "pattern" relays which combinations of links and junctors are allotted for the completion of calls between the particular trunks involved. It tests these combinations (called channels), selects an idle one and proceeds to operate the proper selecting and holding magnets of the two links and the junctor making up this combination. This establishes a connection from the incoming tandem trunk to the selected outgoing trunk.

4. When the marker has completed these operations it checks the connection to assure that it is properly established and that it will hold from the tandem trunk circuit.

5. From information furnished by the route relay, the marker transmits to the sender the following information:

(a) Class of outpulsing—that is, revertive, call indicator or dial.

(b) Compensating resistance. Compensating resistance is necessary for revertive pulsing since the pulsing loops must be kept within certain resistance limits.

(c) Office brush and office group selections. These selections are required by the dial and multifrequency senders when these senders complete through an office selector tandem or through a second crossbar tandem on a revertive basis.

(d) Fifth and sixth step-by-step digits.

6. When the marker has completed its operation, it sends a release signal to the sender which causes the sender to release the marker connector and the marker. The marker on releasing releases in turn the office and trunk link connectors.

Wide flexibility in the assignment of trunks on the office frames and in the size of trunk groups is provided by the marker design. Alternate routing arrangements are also provided which permit the establishment of connections over other routes if the normally used groups are busy.

Trunks

Incoming trunks are arranged for local type loop supervision or for toll type composite, simplex or voice frequency supervision. Trunks used for toll traffic are provided with means to permit re-ring from the originating end, a necessary feature for toll operation.

An important feature provided in trunks coming from panel offices is remote control of zone charging. Zone charging involves the operation of the subscriber's message register one or more times on a single call, depending upon the initial charge for the call and also on the length of the conversation. Although the local panel circuits can be arranged for this feature it is much more economically accomplished by determining the charge at the tandem office and then operating the message register by signals passed over the trunk to the local office. The trunks are arranged to receive information from the marker, through the trunk link connector, as to the charge rate, that is, the number of times the message register should be operated for the initial and overtime periods together with the length of the initial and subsequent talking periods permitted on that call. At the beginning of the initial period the predetermined number of charge signals is sent back to the local tandem office over the tip and ring in such a way as not to disturb the talking circuit.

The tandem trunk also times the conversation and again operates the message register the required number of times for the overtime period. The function of the marker in this connection is to determine

and set up in the trunk the proper charge combinations. This is done in the following manner: a contact on the route relay operates one of 30 "zone" relays, each having ten pairs of contacts, the ten corresponding armatures of these relays are multiplied together and these ten leads, called zone leads, are run to the trunk link frames. Each selecting magnet on the primary crossbar switch of the trunk link frame is associated with an incoming trunk.

By cross-connecting the winding of the selecting magnet to one of the zone leads the incoming trunk can be identified by the marker as coming from one of ten zones. Likewise the outgoing zone is identified by the operated zone relay in the marker. The ten contacts on each of the 30 zone relays (total 300 contacts) are cross-connected to control the setting of the proper charge relays in the trunk.

Maintenance Features

The arrangements for maintenance of crossbar tandem are very similar to those in the Number 1 system. Routine test frames are provided for the senders and outgoing trunks. The incoming trunks can be tested from the trunk test boards of the originating offices and also by means of portable test sets at the tandem office. These test circuits apply marginal operations to the various circuits. The routine test frames perform these tests automatically and if trouble is encountered the tests are stopped and an alarm given to the maintenance force.

The marker is provided with many self-checking features which are applied while a call is being handled. If trouble is encountered, the marker automatically connects momentarily to a recording circuit called the "trouble indicator." Relays operated in the trouble indicator light lamps which enable the maintenance force to locate the trouble.

Figure 9. Crossbar tandem maintenance center

Figure 9 shows the crossbar tandem maintenance center. The bays from left to right are sender test, sender make busy, trouble indicator, and three bays of trunk test circuits.

Power Plant

The principal power required by the crossbar tandem is 48 volts, direct current, which is used for the operation of practically all the signaling and transmission circuits. Several other sources of direct current are furnished for miscellaneous purposes. Individual frame filters are connected across the 48-volt power supply leads at the frames where noise-free battery supply is required for talking circuits.

Conclusion

There are at present about 30 installations of crossbar tandem throughout the country. Some of these are furnishing local tandem facilities in strictly step-by-step areas where the flexibility of the trunking arrangements is of particular advantage over the step-by-step tandem system.[6]

Installations in other areas are furnishing means or interconnecting the local manual, step-by-step, crossbar and panel offices. A number of offices are handling primarily toll terminating traffic where advantage is being taken of the ability of crossbar tandem to receive multifrequency pulsing over long toll lines.

This feature permits toll operators to complete calls through crossbar tandem in distant cities without the assistance of terminating operators.

An extensive development program now is in progress to incorporate new features which will still further enhance the usefulness of crossbar tandem in the rapid expansion of automatic switching in the Bell Telephone System.

The Design of Broad-Band Transformers for Linear Electronic Circuits

H. W. LORD
MEMBER AIEE

WHEN designing linear amplifier circuits, the designers often find it highly desirable to take advantage of the impedance-matching and phase-inverting properties of transformers. However, they sometimes fail to realize that even a well-designed transformer may not be able to pass the required band of frequencies when connected between the available power source and specified load. At other times they may ask for impedance or phase characteristics which are unrealistic or which call for unnecessarily close tolerances.

The designers of the transformers which the electronic circuit designers need do not always appreciate the manner in which certain transformer characteristics influence the over-all frequency response of the combined transformer and linear-amplifier circuit. Another little known factor is the manner in which the transformer contributes to the harmonic distortion.

So long as the electronic circuits were required to handle band widths of only a few kilocycles, this lack of understanding was not serious. However, the advent of high standards of performance for both amplitude modulation and frequency-modulation transmitters and studio equipment soon made this difficulty very apparent. The electronic circuit designers complained that it was very difficult to obtain completely satisfactory transformers for their equipment. They almost invariably had to go through a long series of developmental samples on small units before obtaining satisfactory transformers. On the larger modulation transformers, they usually had to incorporate a series of compensating and equalizing networks in their circuits in order to obtain satisfactory over-all performance. On the other hand, the transformer designers complained that the specifications given them by the electronic engineers were often incomplete or unrealistic. Furthermore, they claimed that their designs would often test satisfactorily in the low-power or equivalent test circuit specified by the electronic engineers and then give unsatisfactory performance under actual operating conditions.

This state of affairs was brought to the attention of the writer in the early part of 1947. A review of the pertinent literature available at that time[1,2] revealed no really satisfactory answer to the general problem, so a project directed toward rectifying this condition was initiated in the General Electric Research Laboratory. A book[3] published several months later covers this subject fairly well. However, the approach to the problem to be described here offers some advantages over that described in these references. One of the objectives of this project was to provide some common meeting ground between electronic-circuit engineers and transformer-designing engineers. Information was to be provided which would enable the designers of broad-band linear amplifier and transmission circuits to determine the practicability of using transformers to obtain certain desired results and to make proper and realistic requirement specifications to convey their needs to the transformer designer. Also, the information was to be such as to enable transformer designers, given these requirement specifications and electronic circuit operating conditions, to determine the feasibility of designing the required transformers and to predict with reasonable accuracy the performance of the transformers when combined with the circuits.

Development of a Terminology

Perhaps the main barrier to the free exchange of information between these two groups of engineers has been that of terminology or language. For example, the electronic-circuit designers use such terms as coefficient of coupling, primary inductance, secondary inductance, and circuit Q to express some of the characteristics of transformers in electronic circuits. Since most audio and power transformers have very tight coupling between the primary and secondary, it is more convenient for the transformer designers to express these characteristics in terms of leakage inductance, magnetizing inductance, and load resistance.

In order to have the analysis cover the most general case, the transformer-coupled modulator with shunt-feed reactor was chosen as representative, since it requires consideration as a coupling net-

Paper 50-159, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif, June 12–16, 1950. Manuscript submitted March 13, 1950; made available for printing April 18, 1950.

H. W. LORD is with the General Electric Company, Schenectady, N. Y.

The author acknowledges and appreciates the help of the several associates within the General Electric Company whose co-operation has made this paper possible. These include R. A. Dehn, S. G. Reque, F. A. Pessler, K. Carpenter, Miss W. J. Clelland of the Research Laboratory, C. L. Rounsit of the Electronics Department, C. H. Wells of the Power Transformer Engineering Division, and V. R. Peterson of the Specialty Transformer Engineering Division. Part of the work forming the basis for this paper was supported by contracts with the Signal Corps Engineering Laboratories, Fort Monmouth, N. J.

work at both ends of the pass band.

Figure 1 is the general equivalent circuit of such a modulator, where

E_1 = voltage generated in plate circuit of final amplifier tube
R_p = plate resistance of final amplifier tube
C_p = total primary shunt and distributed capacitance
L_p = primary leakage inductance
R_c = equivalent resistance corresponding to core losses
L_m = equivalent magnetizing inductance of primary
T_r = ideal transformer of primary-to secondary ratio of $1/r$
L_s = secondary leakage inductance
C_s = total shunt and distributed capacitance of transformer secondary and modulation inductor
C_c = coupling capacitance between transformer and modulation inductor
L_L = modulation inductor (shunt-feed inductor)
C_L = radio-frequency by-pass capacitor plus capacitance of wiring
R_L = equivalent resistive load of radio-frequency amplifier

If it is assumed that the winding resistances and core losses are negligibly small, that the coefficient of coupling is practically unity, and that any primary-to-secondary capacity effects are negligibly small, then Figure 2 will be recognized as the general equivalent circuit, where all circuit values such as shunt-feed reactor, load, and so forth, are referred to the primary. The circuit elements in Figure 2 are as follows

L_1 = total transformer leakage inductance referred to primary $= L_p + L_s/r^2$
L_2 = primary exciting inductance $= L_m$
L_3 = inductance of shunt-feed reactor referred to primary $= L_L/r^2$

Figure 4. Generalized frequency-response characteristic

Output voltage at low frequencies

Figure 2 (left). General equivalent circuit of modulation system reduced to unity ratio and referred to the transformer primary

Figure 3 (right). Simplified equivalent circuits for limited frequency ranges

C_1 = total shunt capacitance of load, shunt-feed reactor, and transformer $= r^2(C_S + C_L)$
C_2 = capacitance of coupling capacitor referred to primary $= r^2 C_c$
C_3 = total shunt capacitance of transformer primary and wiring $= C_p$
R_1 = equivalent resistance load referred to primary $= R_L/r^2$

Since the analysis is to apply to transformers having broad-band characteristics, the equivalent circuit can be simplified by dividing the frequency range into three sections—low, medium, and high frequency. The medium-frequency region is the band over which the reactive elements have negligible effect and so the simple circuit of Figure 3(A) holds true. At high frequencies the effect of the series inductances and shunt capacitances are all that need to be considered; hence the equivalent circuit at the high-frequency end of the pass band becomes that of Figure 3(B). At low frequencies only the shunt inductances and series capacitances need to be considered; hence the equivalent circuit of Figure 3(C) is valid. These equivalent circuits now represent the transformer and circuit as relatively simple networks made up of elements of resistors, inductors, and capacitors.

In order to obtain a simple terminology for expressing the interrelationship of these elements, it seemed desirable to avoid the use of such frequency-dependent factors as Q (quality factor) and D (dissipation factor). This can be done if the reactive elements L and C of the networks are treated as elements of an artificial line of characteristic impedance Z_0 defined by the expression $Z_0 = \sqrt{L/C}$. This term is commonly used in connection with pulse-transformer design[4]; so it seems reasonable to apply it to broad-band-transformer design. If the circuit of Figure 3(B) is treated as an artificial line, it will have a characteristic impedance Z_{01} equal to $\sqrt{L_1/C_1}$. Figure 3(C) also can be considered as an artificial line of characteristic impedance Z_{02} equal to $\sqrt{L_3/C_3}$. These circuit constants can be conveniently related to frequency by the equation for electrical resonance. Thus, for the high-frequency circuit, $2\pi f_{01} = \omega_{01} = 1/\sqrt{L_1 C_1}$, and for the low-frequency circuit, $2\pi f_{02} = \omega_{02} = 1/\sqrt{L_3 C_3}$. These terms are applicable even if the capacitor C_3 and inductor L_3 are of such values that they can be neglected.

This terminology for describing the equivalent circuits of the transformer, their relations to each other and to frequency, is easily understood by both electronic circuit designers and transformer designers. It employs nothing which is unfamiliar to the circuit designers since it avoids such terms as magnetizing reactance and leakage reactance. The term characteristic impedance may be new to some transformer designers. However, its definition is relative simple and experience indicates that transformer designers accept this term more readily than they accept the terms Q and D.

Figure 5. Generalized frequency-response characteristic

Output voltage at high frequencies

Figure 6. Generalized frequency-response characteristic

Input impedance at low frequencies

Generalized Response Curves

Having established a terminology, the equivalent circuits representing several types of coupling transformers at the high and low regions of the band pass were analyzed relative to such important frequency response characteristics as output voltage, output phase, and input impedance. Because of space limitations, the results of only a few of those analyzed are shown here as examples of this phase of the project.

Perhaps the most important characteristic of the combined amplifier and transformer is the manner in which the ratio of the output voltage to the input voltage varies with frequency. In many instances the allowable variation of this ratio over the useful portion of the pass band must be held to a very constant value. For example, it is not uncommon in audio-amplifier circuits to require that this voltage ratio be held constant within $\pm 1/2$ decibel (± 6 per cent) from 20 cycles to 20,000 cycles. Figures 4 and 5 illustrate the theoretical generalized frequency response curves of this voltage ratio for several ratios of tube plate resistance to equivalent load resistance. Note that the frequency parameter is expressed as a ratio so as to be applicable to any frequency range that may be determined by the equivalent circuit constants. The particular equivalent circuit analyzed to obtain each set of curves is shown schematically in each illustration.

Another important characteristic is the impedance presented to the tube by the combined transformer, coupling network when used, and load. Figure 6 and Figure 7 show the manner in which the impedance characteristic varies with frequency. Large dips in impedance within the normal operating range must be avoided since they tend to increase the distortion in the associated amplifier tubes.[9] However, a large increase in impedance occurring at either end or both ends of the pass band can be tolerated. The curves of Figure 6 and Figure 7 provide means for selecting the proper ratio of the characteristic impedance to the load resistance. They show that when $Z_0/R_1 = 1.25$, the impedance within the normal operating range drops to only 88 per cent of the mid-frequency value. Since this ratio usually provides the best compromise between the impedance characteristic and the output-voltage characteristic, the frequency-response curves which were selected to illustrate this paper are for this optimum ratio.

Except when a feedback loop includes the transformer, the phase angle of the output voltage with respect to the input voltage as a function of frequency is of little importance in many audio amplifiers. This phase angle is important in video amplifier circuits for radar and television. Figure 8 and Figure 9 show frequency response curves of this characteristic.

Specifications Required

In order to design a transformer using these theoretical curves, the circuit designer must provide the transformer designer with certain specifications which adequately describe the circuit in which the transformer is to be used and the overall performance required. An outline of the essential specifications follows:

1. Circuit Characteristics
   - A. Load
     - *i.* Equivalent load resistance
     - *ii.* Total value of shunt capacitances
     - *iii.* Required maximum audio power into load
     - *iv.* Component of direct current into load
   - B. Power Source
     - *i.* Characteristic impedance for a line or cable
     - *ii.* For an amplifier—single-ended; push-pull, class *A*, or class *B*
       - a. Minimum average plate resistance (this should include the effect of feedback in modifying the actual plate resistance)
       - b. Plate current at zero signal and maximum signal; maximum unbalance if push-pull
       - c. Peak plate current
       - d. D-c plate-supply voltage
       - e. Peak-to-peak plate voltage swing
2. Transformer Characteristics
   - A. Secondary
     - *i.* Maximum allowable winding resistance
     - *ii.* D-c component of voltage to ground
     - *iii.* Peak-to-peak voltage swing or rms value of alternating-voltage component
   - B. Primary
     - *i.* Maximum allowable winding resistance
     - *ii.* Normal value of impedance presented to power source with load connected
   - C. Minimum Allowable Efficiency
3. Over-All Performance of Transformer and Circuit
   - A. Frequency-Response Characteristics
     - *i.* Load voltage
       - a. Amplitude versus frequency
       - b. Phase versus frequency when required
     - *ii.* Primary impedance (minimum allowable within operating range, as per cent of normal)
     - *iii.* Signal amplitude (maximum required input signal in per cent of normal as a function of frequency)
   - B. Harmonic Distortion (maximum allowable attributable to the transformer, excluding that caused by impedance effects)

Figure 7. Generalized frequency-response characteristic

Input impedance at high frequencies

Outline of Design Procedure

A design procedure is fairly straightforward when based upon these generalized response curves and a suitable set of specifications covering the transformer and circuit performance requirements. First, the required transformer turns ratio 1/r of the primary to the secondary is calculated from the specified transformer ratings and used to determine an equivalent value for the resistive component of the load as reflected to the primary. Then the ratio of this reflected load resistance to the average effective plate resistance of the amplifier tube, as given by the specifications, provides the necessary

Figure 8. Generalized frequency-response characteristic

Output phase at low frequencies

Figure 9. Generalized frequency-response characteristic

Output phase at high frequencies

Figure 10. Circuit diagram of push-pull class-B amplifier

Used for harmonic distortion tests

information to select the particular generalized frequency response curve which should be used at each end of the pass band. These two curves are then employed to determine values for the magnetizing inductance, the total leakage inductance, and the allowable secondary shunt capacitance, in the following manner.

For illustrating this procedure, assume the transformer is coupled to the load through a shunt-feed inductor and coupling capacitor. Their equivalent primary values, as well as the transformer magnetizing inductance, can be determined from Figure 4 and the specified low-frequency response characteristic. For example, suppose the reflect load resistance, R_1, is 10,000 ohms, the effective plate resistance, R_p, is 20,000 ohms, and the output voltage must be no more than one decible down at 50 cycles. The curve for the ratio of $R_p/R_1 = 2$ of Figure 4 is then the one to use. The output voltage for this curve is down one decibel from the mid-frequency value of -9.5 decibels at ω/ω_{o2} of 0.72, from which $\omega_{o2} = 2\pi \times 50/0.72 = 437$. Since these curves are for $Z_{o1}/R = 1.25$, then $Z_{o1} = 12{,}500$. The expressions $Z_{o1} = \sqrt{L_1/C_1}$ and $\omega_{o1} = 1/\sqrt{L_1C_1}$ can be combined to give the expressions $L_1 = Z_{o1}/\omega_{o1}$ and $C_1 = 1/Z_{o1}\omega_{o1}$; $L_1 = 12{,}500/437 = 28.6$ henrys is therefore the required reflected value for the shunt-feed inductor. It is desirable that the transformer-primary magnetizing inductance be equal to this same value. The required shunt-feed choke is then $r^2 \times 28.6$ henrys. Also, $C_1 = 1/12{,}500 \times 437 = 0.183$ microfarad is the required reflected value for the coupling capacitor. The required coupling capacitor is then $0.183/r^2$ microfarad. If the primary capacitance is small and so assumed to be negligible, then Figure 5 can be used in a similar manner to determine the total equivalent primary leakage inductance and total allowable secondary and load shunt capacitance. The curve for $R_p/R_1 = 2$ shows the output voltage is down one decible from the mid-frequency value of -9.5 decibels at ω/ω_{o1} of 0.88. If this point is assumed to be specified as the 10-kc point in the specified over-all frequency-response characteristic, then $\omega_{o1} = 2\pi \times 10{,}000/0.88 = 7.14 \times 10^4$. Hence, the total equivalent primary leakage inductance L_1 should be $12{,}500/7.14 \times 10^4 = 0.175$ henry and the total allowable reflected secondary and load shunt capacitance C_1 should be 0.00112 microfarad. If the specifications call for operating with a shunt capacitance across the load of C_L microfarads, then the total shunt and distributed capacitance C_s allowed for the transformer secondary and shunt-feed inductor will be found by the expression $C_s = C_1/r^2 - C_L$ microfarads.

All of the transformer design constants which affect the frequency-response characteristic have now been determined. From here on the design follows the conventional procedure. The problem becomes one of designing a transformer which will have these constants and which will have sufficient core area and copper cross section to handle the power level as specified for certain frequency ranges within the pass band. In general, the core area is determined by the low-frequency requirements; so the trans-

Figure 13. Over-all amplifier frequency response characteristic

Variation of ratio of input voltage to output voltage as measured and as predicted by equivalent circuit analysis

former is first designed with sufficient core area and coil turns to satisfy the specified power conditions at the low-frequency end of the pass band and with the required value of magnetizing inductance. The coil configuration and arrangement of windings are then varied to obtain the required value of leakage inductance. Finally, the secondary distributed and shunt capacitance are calculated. If these turn out to be too high, then the secondary coils may have to be arranged in piles. In order to obtain a satisfactorily low capacitance value without an increase in leakage inductance caused by increasing the spacings between windings and layers, it may be necessary to start a new design with a larger core area.

Harmonic Distortion Attributable to Transformer

Circuit designers must design systems with harmonic distortions below specified maximum values. The transformer, as a component of the system, must be so designed as to contribute only a fraction of the allowable over-all distortion.

It has been recognized for some time in class-*B* push-pull amplifiers[5] that the leakage inductance between the two halves of the primary winding is a source of distortion in the high-frequency portion of the pass band. However, of the only two references found, one[6] assumed linear transfer characteristics for the tubes; hence the theoretical analysis given could not be relied upon for numerical results for a practical amplifier. The other[3] stated that perceptible nicks in the output voltage wave would occur if the ratio of primary-to-primary leakage reactance to average triode plate resistance is four or more. This sort of information is inadequate since modern amplifiers often have tetrodes or pentodes in the output stage and their plate resistance is usually very high. Also, many amplifiers now employ inverse voltage feedback to keep the amplifier distortion low and ten decibels of this type of feedback reduces the apparent plate resistance to a relatively low value[8]. Reduction of this leakage inductance to very low values usually requires complex interleaving of the windings. This is not only expensive but may also introduce undesirable capacity effects between winding sections. It is therefore advantageous to be able to determine with reasonable accuracy a value for this leakage inductance which will keep the distortion caused by it below a specified value.

Since the analytical solution of this problem was complicated by nonlinear circuit elements, it was solved experimentally. A transformer was constructed with several windings of equal turns so that the leakage inductance between halves of the primary as well as that between half-primary and secondary could be varied by changing the winding arrangements. Capacity effects were minimized by operating both primary and secondary at low levels of impedance. The apparent plate resistance of the class-B push-pull amplifier was made very low by operating tubes in parallel and by employing a large amount of inverse voltage feedback from the plates. This feedback also reduced the amplifier harmonic distortion to a relatively small value.

Figure 10 shows the schematic circuit diagram of the test circuit. Leakage inductances for each arrangement of transformer connections were measured and the value of the padding capacitor across the 600-ohm load adjusted so that the equivalent circuit of the transformer and load conformed to that shown on Figure 5. Tests of output voltage of the combined transformer and test circuit as a function of frequency were made for each connection and compared with the theoretical curves as a check of conformity with the equivalent circuit. Harmonic distortion at the high-frequency end of the pass band was then measured for each connection arrangement. Results of the harmonic distortion tests were plotted as shown in Figure 11, using a dimensionless frequency parameter in order to provide a means for readily comparing these data.

Figure 11 indicates that the harmonic distortion in each case reaches a maximum value at a frequency which is approximately one-half the resonant frequency of the circuit and transformer.

Since the leakage inductance between one-half of the primary and the secondary is one of the key values in determining the output voltage versus frequency-response characteristic, it seemed desirable to try to relate the distortion to this parameter also, instead of to the plate resistance of the amplifier. By using the ratio of the leakage inductance between halves of the primary to the leakage inductance between one-half primary and secondary, this parameter can be made dimensionless for purposes of generalization. Curve *A* of Figure 12 was obtained by plotting the harmonic distortion values of the peaks of the curves of Figure 11 against the corresponding inductance ratios for each of those curves. Except for the effect of the small value of residual harmonic distortion due to the amplifier, there is a linear relationship between the inductance ratio and the maximum value of harmonic distortion it produces.

It is frequently assumed that harmonic distortions of these low values can be added and subtracted arithmetically. If

the residual distortion is subtracted, then curve *B* of Figure 12 indicates the amount of harmonic distortion which transformers of various values of leakage-inductance ratios will contribute to the circuit. These distortion values apply only to amplifiers with plate feedback. This probably represents the case most susceptible to this type of distortion; so these distortion values are greater than those introduced by a given transformer when operating from class-*B* push-pull amplifiers employing triodes, tetrodes, or pentodes without inverse voltage feedback from the plates.

Another source of distortion which the transformer may contribute becomes evident at the low end of the pass band. This distortion is caused by the harmonic content in the magnetizing current required by the transformer core. Methods of calculating such distortions have been suggested,[7,8] although they are rather laborious.

Application Results

A series of some 30 generalized frequency-response curves similar to those of Figures 4 through 9 were prepared for the use of designing engineers of the General Electric Company. These were based upon the theoretical analysis of several equivalent circuits and ratio of parameters.

Before turning this information over to the designing engineers, it was deemed advisable to provide some evidence that the information could be used as a basis for designing transformers which would perform as predicted by the theoretical analysis of the equivalent circuits. As a test case, the Electronics Department of the General Electric Company furnished performance specifications for a 3-watt tube-to-line output transformer needed for frequency-modulation studio equipment. This was chosen as they had yet to obtain a satisfactory unit after testing a series of seven successive designs of developmental samples. Figure 13 shows the frequency response of the output voltage of the first design made with the aid of the theoretical curves. Several points from the theoretical curves are included to indicate the close agreement between the theoretical curves and that obtained by test of this sample unit in the circuit.

After such good results were obtained on this first design, the information and data based upon this terminology were released to the transformer and electronics-circuit designing engineers. The suggested terminology was readily accepted by both groups. A format of the specification sheets for audio transformers was modified by the electronic engineers to permit the use of this new approach to the problem. It then became relatively easy for the transformer designers to use the generalized response curves to convert these specifications into design constants for the required transformer. Transformer designers with no previous experience in audio-transformer design are now able to turn out designs which yield a high percentage of satisfactory first models.

Both groups have benefited through the use of these design data. The transformer designers now receive specifications which are complete and which accurately describe the needs of the circuit designers. First developmental models of small units usually perform satisfactorily in the circuit, thus materially shortening the time the circuit designer must spend upon circuit development and testing. The size and weight of large modulation transformers have been reduced. In some cases this size reduction has improved the high-frequency characteristic to such an extent that satisfactory performance is obtained without the addition of compensating and equalizing networks.

Although the examples of this paper have been based upon audio transformers, the curves, data, and design procedures described are generally applicable to video transformers and other broad-band transformers. Circuit designers are continually asking for broad-band transformers of unusual characteristics, specifying operation in a band of frequencies which may lie within the range of a few cycles to several hundred megacycles. The time required to design and develop transformers to meet their needs is materially shortened through application of these techniques.

Principles of Design of Log-Scale D-C Indicating Instruments

ALLEN STIMSON
ASSOCIATE AIEE

C. F. TAYLOR
NONMEMBER AIEE

IN MANY quantities, such as money, equal increments are of equal value regardless of the total amount. In other quantities, the increment is evaluated in relation to the total amount. Physical sensation is one example. According to the Weber-Fechner law, a stimulus which increases in geometric progression, produces a sensation which increases in arithmetic progression. This means that the magnitude of the stimulus determines the importance of its increment. For instance, an increment of one foot-candle added to illumination of five foot-candles would noticeably increase visibility. Yet one foot-candle added to one hundred foot-candles would not be perceptible. The eye is equally sensitive to equal percentage differences. A lightmeter should, therefore, give equal per cent reading accuracy at each scale point. An instrument having this distribution has a logarithmic scale. Sound is also evaluated on a logarithmic basis expressed in the familiar decibel units.

In conventional d-c indicating instruments the scale distribution is linear. Each minor scale division represents an equal increment of current. In an instrument having logarithmic scale distribution, each minor scale division represents an equal per cent of the corresponding scale value.

Log-scale instruments are of value when the entire scale range should be readable with equal accuracy as in an ammeter. For a voltmeter, used on established circuits, the log-scale would be of less usefulness, because only values near the rated voltage would be read.

The advantages of the log-scale distribution may be summarized

1. Equal per cent reading accuracy throughout the scale range.
2. Better reading accuracies in the lower half of the scale.
3. Larger scale ranges are possible.
4. Higher deflection sensitivity near zero for the same full scale rating.
5. The logarithmic scale can function as part of a slide rule with the instrument pointer performing the computation.

Log-scale instruments also have certain disadvantages compared to linear-scale instruments

1. They are more expensive.
2. For equal full-scale rating the log-scale instruments require more power.
3. Unit increments near full scale are not so readable.
4. Variation in magnetic damping with scale deflection may make some dynamic characteristic harder to obtain for certain applications.

Mathematical Background

An electrical indicating instrument which provides equal reading accuracy at all scale points, expressed in per cent of the indicated value, must have a unique scale distribution. The change in scale values per unit angular pointer movement must be proportional to the scale value. If the scale is calibrated for signals x and the pointer deflection is θ, then

$$\frac{dx}{d\theta}=\frac{x}{c_1} \tag{1}$$

or

$$d\theta=c_1\frac{dx}{x} \tag{2}$$

The solution of differential equation 2 is

$$\theta=c_1 \log x+c_2 \tag{3}$$

Equation 3 expresses the general scale law of log-scale instruments.

For the purpose of this discussion it is assumed that an instrument is to be designed having the predetermined scale values defined by equation 3 and shown in Figure 1. The scale has the following characteristics when the base of the system of logarithms is a

Scale range per log cycle $=a$
Number of log cycles in scale range $=n$
Scale range of instrument in log cycles $=a^n$
The scale range in terms of values of the signal x is

$$\frac{x_F}{x_0}=a^n \tag{4}$$

The derivation of equation 3 defines the logarithm to the base e. However, change to any base a merely changes the value of the constant c_1. The example, Figure 1, arbitrarily assumes the base to be $a=2$.

The values of the constants c_1 and c_2 may be determined from the boundary conditions. When

$$x=x_0,\ \theta=0 \tag{5}$$

When

$$x=x_F,\ \theta=\theta_F \tag{6}$$

If the limits of equations 5 and 6 are substituted in equation 3 the constants are found to be

$$c_1=\frac{\theta_F}{\log\frac{x_F}{x_0}} \tag{7}$$

and

$$c_2=-\frac{\theta_F \log x_0}{\log\frac{x_F}{x_0}} \tag{8}$$

From equation 4 it is evident that

$$\log_a\frac{x_F}{x_0}=\log_a a^n=n \tag{9}$$

Paper 50-160, recommended by the AIEE Instruments and Measurements Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 13, 1950; made available for printing April 18, 1950.

ALLEN STIMSON and C. F. TAYLOR are with the General Electric Company, West Lynn, Mass.

Figure 1. The predetermined scale distribution is defined by this logarithmic relation

Figure 2. The instrument current is related to the signal by this arbitrary function

Figure 3. The total restoring torque is the sum of the torques due to control springs, parasitic iron, and ferromagnetic controls

Equations 7 and 9 then become

$$c_1 = \frac{\theta_F}{n} \tag{10}$$

$$c_2 = -\frac{\theta_F}{n} \log x_0 \tag{11}$$

The significance of c_1 is the pointer deflection per cycle, and it is also the slope of the curve of Figure 1. The constant c_2 is the value of θ when $x=1$ and $\log x=0$. Equation 3 may now be written

$$\theta = \frac{\theta_F}{n}(\log_e x - \log x_0) \tag{12}$$

$$\theta = \frac{\theta_F}{n} \log_e \frac{x}{x_0} \tag{13}$$

Equation 13 expresses the general scale law for an instrument having logarithmic scale distribution. It states that equal increments of pointer deflection θ represent equal increments of $\log x$.

In designing an instrument to track equation 13 it is assumed that the signal x is related to the instrument current i by a function

$$i = f_1(x) \tag{14}$$

and which may be an empirical relation of the type shown in Figure 2. In this graph, values of both θ and x are shown according to the relation assumed in Figure 1. For any particular case the function

$$i = f_2(\theta) \tag{15}$$

is also known from Figure 1.

A d-c instrument at steady state indication is subject to the electromagnetic deflecting torque

$$T_D = BSNi \tag{16}$$

From this well-known relation, the flux density may be found. For a log-scale ammeter where the signal is i and the restoring torque is $K\theta$, the flux density from 13 and 16 is

$$B = \frac{T_R}{SNi} \tag{17}$$

$$B = \frac{K}{SNi_0} a_{Bi}^{-\frac{n}{\theta_F}\theta} \tag{18}$$

The graph of this equation is similar to that in Figure 4. For an actual instrument the nonlinear restoring torque of Figure 3 is the sum of several components arising from iron in the moving system in addition to the control springs.

$$T_R = T_S + T_P + T_M \tag{19}$$

The current i may also be nonlinearly related to the signal X as in equation 14. Values of B are calculated point by point from equation 17 using values of i com-

Nomenclature

a = Scale constant (log base)
B = Radial component of magnetic-flux density, gauss
B_1 = Flux density B at angle θ_1, gauss
B_1' = Flux gradient $dB/d\theta$ at angle θ_1, gausses/radian
B_F = Flux density B at full scale, gauss
B_{max} = Maximum flux density at angle $\theta = M$, gauss
C_1 = Scale constant (θ_F/n)
C_2 = Scale constant $\left(-\frac{\theta_F}{n} \log x_0\right)$
C_3 = Damping shell constant $= \frac{D}{B^2}$, $\frac{\text{dyne-centimeter-second}}{(\text{gauss})^2}$
C_4 = Constant $= SNi_1(B_1 - \theta_1 B_1')$, dynecentimeters
D = Damping constant, dyne-centimeter-second
D_1 = Damping constant at angle θ_1, dyne-centimeter-second
f_0 = Undamped frequency of oscillation, $(\text{second})^{-1}$
f_d = Damped frequency of oscillation, $(\text{second})^{-1}$
i = Current in moving coil, ampere
i_1 = Current causing deflection θ_1, ampere
I = Moment of inertia of moving system, gram-centimeter^2
K = Control spring constant, dyne-centimeter/radian
n = Number of log cycles on scale
N = Number of turns on moving coil
S = Torque per ampere turn per kilogauss
T = Torque (general), dyne-centimeters
T_L = Deflecting torque, dyne-centimeters
T_M = Torque due to iron vane on moving system, dyne-centimeters
T_P = Parasitic torque due to magnetic impurities in moving system, dyne-centimeters
T_R = Total restoring torque, dyne-centimeters
T_S = Torque due to control springs, dyne-centimeters
T_1 = T_S at θ_1, dyne-centimeters
W = Weight of moving system, grams
x = Signal calibrated on instrument scale
x_0 = x at $\theta = \theta_0$
x_F = x at $\theta = \theta_F$
θ = Scale angle, radians
θ_F = Full-scale angle, radians
θ_M = Angle at maximum flux B_M, radians

Figure 4. The variation of flux density in the path of the moving coil has a unique pattern for log-scale instruments

Figure 5. A conventional expanded scale instrument

puted from equations 13 and 14 and values of T_R from equation 19. Figure 4 shows the flux distribution for an actual design.

Design of the Magnetic System

The distribution of the effective flux density B along the path of the moving coil is one parameter which can be controlled. The method of design of the magnetic system will be illustrated by a general example.

The signal x to be measured is manifested by a current i having an arbitrary relation shown in Figure 2. Inasmuch as Figure 1 has shown the desired scale law relating θ and x, the corresponding values of θ are also shown in abscissas in Figure 2.

The instrument mechanism selected for this application has a known torque S per ampere turn per kilogauss of B and a moving coil of N active turns. It is then easy to compute values of the product SNi from the data in Figure 2 for various values of θ.

The instrument mechanism selected may be assigned trial torque characteristics. These are illustrated in Figure 3 and consist of the control spring torque T_R, the parasitic torque T_P due to distributed magnetic impurities in the moving system, and the other torques T_M due to a magnetic vane and possible polarized pivots. At each value of θ the summation of torques T_R has the unique value of equation 19 shown in Figure 3. The numerical values of these torques must be initially assumed for the purpose of evaluating the corresponding flux distribution.

Figure 6. The magnetic structure of a log-scale instrument

The required distribution of the radial component of flux density B is calculated from equation 17 by dividing the values of T_R by the corresponding values of SNi for each value of θ. The resulting unique function of B is plotted in Figure 4.

This distribution of flux in the air gap, Figure 4, is based on assumed torques of Figure 3. The moving-iron torques T_P and T_M are dependent upon the flux distribution and must therefore be recomputed or measured for the actual flux distribution. The new values may demand a second computation of the required flux distribution.

Characteristics of the Flux Distribution

The design of a magnetic system which will provide the flux-density distribution of Figure 4 is limited by several practical considerations. The density cannot be zero at scale zero, $\theta=0$, because there will be a minimum stray field which cannot be avoided. Hence, the actual log-scale distribution must start at some small angle above scale zero. If B were zero at scale zero, initial deflection of the moving system could never result from any current i according to equation 16. The initial deflecting torque would be zero and the response time would be infinite.

The steepness of the gradient of the air-gap flux density $dB/d\theta$ between points P and Q in Figure 4 is limited by the actual length of the path of the moving coil and the value of B_{max}. The longer the path the easier the density can be controlled. The maximum range of the instrument is also limited by the minimum flux density B_P which can be obtained at the full-scale position of the moving coil.

The higher the value of the maximum flux density, B_{max}, the higher the sensitivity of the instrument and the greater the possible scale range. Instruments can be designed for values of B_{max} over 6,000 gausses but the resulting high flux-density gradient increases the highly variable parasitic torques to an uncontrollable level.

The design of the air gap of a conventional expanded-scale moving-coil d-c instrument is shown in Figure 5. This construction can be made to fit part of the characteristic of Figure 4 but only for short scale angles and small ranges. High flux gradients cannot be obtained with this construction in conformance with the required distribution.

Figure 7. The negative gradient of flux density in a log-scale instrument increases the incremental restoring torque

The sharp peak of flux density at B_{max} Figure 4, indicates that the field magnet should have salient poles as at A in Figure 6. The steep gradient at N, Figure 4, suggests that the core be cut away as at G, Figure 6. To obtain the relatively low density B_P at full scale, both the core and the magnet are spaced away from the locus of the moving coil as at C, Figure 6. The density at C may also be controlled by reducing the depth of the core compared to that at G.

The point of maximum flux density, Figure 4, occurs at about 20-per cent scale deflection. To obtain maximum sensitivity the maximum density should be at zero scale position. It is therefore apparent that a logarithmic-scale distribution gives maximum uniformity of reading accuracy at some sacrifice in sensitivity.

The instrument magnetic system shown

Figure 8. The effective factor of merit of a log-scale instrument is greater than indicated by $T/W^{1.5}$ and varies with scale deflection

in Figure 6 was designed for ten degrees deflection per log cycle with log base two. This means that the signal indication is doubled every ten degrees on the scale. The range covered was approximately seven cycles or 128 to 1 within the limits of its logarithmic distribution.

To obtain log distribution of less than ten degrees per cycle would require proportionately higher flux density gradient. This would be obtained by higher flux densities at the poles A within a smaller angular space and greater air gap at C. Soft iron poles would be helpful in concentrating the flux. To obtain log distribution of more than ten degrees per log cycle, the pole faces A would be broadened and the air gaps at C reduced.

It is obvious that the distribution of flux density can be controlled by shaping either the core or magnet poles. Shaping the core has less influence than shaping the magnet poles. The effective flux density can also be controlled by change in the direction of the flux since only the radial component is effective.

The parasitic torques, due to magnetic impurities distributed throughout the moving system, are not noticeable in concentric gap instruments, but do affect the scale distribution with magnetic systems having an effective flux-density gradient.

Scale Tracking Adjustment

There are several methods of reducing the deflecting torque of a permanent-magnet moving-coil d-c instrument to obtain the desired accuracy. One of the most convenient and widely used methods consists of demagnetizing the permanent magnet by application of an alternating field. This method is also quite satisfactory for log-scale instruments.

Demagnetization of a salient-pole magnet changes the restoring torque due to magnetic vanes or parasitic iron in the moving coil. This causes shift of the zero position of the moving coil by an amount which depends upon the per cent reduction of field strength and the magnitude of these torques. The moving-iron torques are in equilibrium with the control springs at the initial rest position. Reduction of field strength reduces these torques also, and the coil moves to a new position of equilibrium. This zero sift is usually not over two or three degrees.

Adjustment by demagnetization must, therefore, be done in two or more steps. The zero position should be checked or reset after each adjustment. The pointer

Figure 9. A log-scale instrument mechanism is used in this new exposure meter

zero always shifts down scale in this type of instrument.

Log-scale instruments do not have the consistent distribution that uniform-scale instruments have. Means for adjusting the distribution in one instrument are shown in Figure 6. The soft iron shunt D is pivoted at E and its affect is controlled by varying the air gap at F. This shunt is so located that it affects only the upper half of the scale.

The log-scale instrument can, therefore, be precisely adjusted at two scale points. The first adjustment is demagnetization at a point in the lower quarter of the scale. Second, the shunt is reduced in effectiveness by increasing the air gap F until a point in the upper quarter scale is correct.

Dynamic Characteristics of Log-Scale Instruments

The magnetic damping and incremental restoring torque vary with pointer deflection in log-scale instruments, whereas they are constant in uniform-scale instruments. The difference is due to the variation in flux density illustrated in Figure 4 and Figure 7.

The motion of the moving system obeys the classical differential equation

$$I\frac{d^2\theta}{dt^2}+D\frac{d_\theta}{dt}+K\theta=T_D \tag{20}$$

The coefficient D is the familiar damping constant, and its numerical value is proportional to the square of the flux density B.

$$D=C_3B^2 \tag{21}$$

In this analysis the ferromagnetic torques are neglected to simplify the derivation. The magnitude of the restoring torque is the important consideration rather than its source. Equation 20 is nonlinear because both D and T_D are functions of B, and B is a nonlinear function of θ. For purposes of analyzing small oscillations of the moving system the relation of B and θ shown in Figure 4, and Figure 7 may be represented by the following approximation of B in powers of θ by Taylor's theorem

$$B=B_1+(\theta-\theta_1)B_1' \tag{22}$$

where

$$B_1'=\left.\frac{dB}{d\theta}\right]_{\theta=\theta_1}$$

If it is further assumed that the velocity $d\theta/dt$ as well as the amplitude is small, then also negligible is the contribution of the variation of B^2 to the variation of the product $B^2\,d\theta/dt$. It can therefore be assumed that B in

$$D_1=C_3B^2 \tag{23}$$

does not vary with θ. It is also seen from equations 16 and 22 that

$$SN_{i_1}=\frac{K\theta_1}{B_1} \tag{24}$$

If equations 22, 23, 24, and 16 are combined with equation 20, then

$$I\frac{d^2\theta}{dt^2}+D_1\frac{d\theta}{dt}+\left(K-\frac{K\theta_1}{B_1}B_1'\right)\theta=C_4 \tag{25}$$

This is the familiar equation for damped harmonic motion. From the known solution of equation 25, the damped frequency of oscillation of the moving system is seen to be

$$f_d=\frac{1}{2\pi}\sqrt{\frac{K-K\theta_1B_1'}{I}-\frac{C^2}{4I^2}} \tag{26}$$

and the undamped frequency is

$$f_0=\frac{1}{2\pi}\sqrt{\frac{K}{I}} \tag{27}$$

For values of θ greater than θ_M, Figure 4 shows that $dB/d\theta=B'$ is negative. Therefore for the greater part of the scale

$$\frac{K-K\theta_1B_1'}{I}>\frac{K}{I} \tag{28}$$

This means that the damped frequency may be higher than the undamped frequency

$$f_d>f_1\Big]_{\theta>\theta_M} \tag{29}$$

In one instrument of this type the damped frequency near full scale was found to be twice the undamped frequency. The additional restoring torques which cause the higher damped frequency are shown graphically in Figure 7.

This additional torque also helps minimize the effect of bearing friction.

It is obvious from the form of equation 25 that the total restoring torque for small deflections $d\theta$ of the moving system energized with current i is

$$T = T_1 + K d\theta - \frac{K\phi_1 B_1'}{B_1} d\theta \qquad (30)$$

The ability of an instrument to overcome the affects of bearing friction is frequently judged in terms of the ratio T/W of torque T to weight W of the moving system. The ratio $(T/W)^{1.5}$ is also considered significant. These factor-of-merit concepts were developed for uniform-scale instruments. In instruments having a gradient of flux density, the value of T is not the spring torque alone but has the additional term added to it as shown in equation 30. This total torque is shown in Figure 7 to provide a greater restoring torque for the instrument having a negative flux-density gradient.

The per cent improvement in effective restoring torque due to the flux gradient is shown graphically in Figure 8. Throughout most of the range the incremental restoring torque of the log-scale instrument is higher than that of the linear-scale instrument.

Example of Log-Scale Instrument

One embodiment of the design principles here outlined, is the new exposure meter shown in Figure 9. Logarithmic-scale distribution was desired so that the instrument scale could function as part of the slide rule for computing exposure from the light indication. Conventional instruments require the photographer to read the scale and then find this value on the slide-rule computer. In this new meter, the log-scale distribution permitted synchronizing the instrument pointer deflection with the slide rule so that neither of these reading operations is needed. This improvement reduces the number of operations, time required, and chances for error to half of those of a conventional exposure meter.

For this particular instrument the signal x is the light to be measured. A typical photovoltaic cell converts this signal to current according to the curve in Figure 2. These log-scale instruments have been manufactured by mass-production techniques with no difficulties from scale distribution.

Conclusion

Instruments having logarithmic-scale distribution provide equal (per cent) reading accuracy at all points; and are especially useful where both high threshold sensitivity and large scale range are desired in one device.

The magnetic system of a log-scale instrument can be designed on the basis of mathematical formulae, which are solved point by point, because the quantities involved cannot be represented by simple algebraic expressions. Initial assumptions of instrument characteristics are used to determine the corresponding ideal distribution of flux density. From the nearest practicable approach to this flux distribution, the corresponding instrument torques are recalculated and the design adjusted accordingly.

Adjustment of scale distribution is usually required to obtain reasonable accuracy. One method of securing the distribution adjustment uses a movable soft-iron magnetic shunt. Adjustment for accuracy of the lower quarter of the scale is obtained by demagnetization. Adjustment in the upper quarter of the scale is accomplished by shunting the flux. The mechanism tracks at mid-scale if the moving system is correctly oriented with respect to the salient magnet poles.

The damping is substantially higher at the lower end of the scale than at the high end. The conventional concept of the ratio of torque T to weight W or $T/W^{1.5}$, known as the factor of merit, is not indicative of the effects of possible bearing friction in a log-scale instrument except near the zero position. The gradient of flux density gives effectively higher restoring torques than the static factor of merit indicates and, therefore, greater freedom from bearing friction errors.

The principles outlined in this paper are applicable to general instrument design. They have been illustrated by specific reference to a new exposure meter, manufactured in large quantities.

Interrupting Ability of Horn-Gap Switches

F. E. ANDREWS
FELLOW AIEE

L. R. JANES
FELLOW AIEE

M. A. ANDERSSON
MEMBER AIEE

A HORN-GAP switch has limitations in its ability to successfully open a circuit because of the restricted space available for the arc. As only meager information applicable to switch operation has been found in the technical literature on arc behavior, an investigation including a large number of field tests has been made by the Public Service Company of Northern Illinois with three principal objectives:

1. To study arc behavior on horn-gap switches under various system conditions.
2. To determine magnitude of currents that can be interrupted on existing switches under prevailing system conditions.
3. To determine basic switch design factors for successful operation under specified conditions.

It is the purpose of the authors to describe this investigation and to present the results and conclusions.

Two basic concepts of arc behavior are generally recognized. One is that arc length is proportional to voltage.[1,2,3] The other is that an unconfined arc should always extinguish itself if clearance permits the required growth to a necessary critical length and the gap is wide enough to prevent restriking. Ackerman[1] has given an explanation of the mechanics of arc extinction and the conditions under which an arc attains the critical length at which it goes out. The increasing length is accompanied inherently by an increase in resistance and a decrease in current.

The length of arc is fundamental in relation to the other variables affecting arc behavior. Arc length is defined as the actual complete length of the irregular circuitous arc path.

It is not the length of the arc, but where it goes, or its spread, that is important in horn-gap switch operation. The clearance or free space available for the spread of the arc must be such that it will not form a short circuit between phases or to ground.

"Reach" has been devised as a measure of the spread to provide a criterion for comparison with switch clearances. Arc reach is defined as the distance from a point midway between the arc extremities to the most remote point of the arc at the time of its maximum length. The reach line is not necessarily perpendicular to switch alignment, but may assume any direction thereto. However, the critical direction of reach is usually perpendicular or nearly so to switch alignment.

The test data are presented on a factual basis and analyzed empirically for use in practical application. No attempt has been made at reconciliation with theory of other arc investigations or justification of the results on a theoretical basis.

Limitations in developing firm conclusions from the available test data are recognized. It is believed, however, that the results from these data are reasonably satisfactory for practical application. Additional tests, preferably indoors, under more definitely controlled conditions would be desirable to evaluate the effects of wind and other presently indeterminate factors.

Previous investigations have yielded information helpful in this study and have provided the equivalent of the following expressions in which L is the arc length in feet; V the arc voltage; and I the arc current.

$$L = \frac{VI^{1/2}}{3{,}000} \qquad (1)$$

$$L = \frac{VI^{1/2}}{3{,}200} \qquad (2)$$

It is seen that both of these formulas are of the same general form in which arc length is proportional to the voltage, but varies with the current according to the exponent shown. However, Monseth and Robinson[3] include the statement, "above 800 amperes the arc voltage seems to become practically independent of the current."

The Edison Electric Institute—Bell Telephone System report on power system faults[2] gives data indicating that arc length is proportional to voltage, that the crest voltage per foot decreases as currents increase up to about 100 amperes crest, and that above this value crest voltage per foot averages about 300, equivalent to 4.7 feet per kilovolt rms. These data were based on coincident instantaneous values obtained from measurements taken at intervals during the arcing period.

The foregoing references provide a basis for using the proportionality of arc voltage and arc length in this investigation. However, they lack agreement on relation of current and arc length. This can be seen by referring to Figure 9 in which curves representing equations 1 and 2 have been plotted for comparison with the data of this study.

The most practical approach to the problem of interrupting arcs on horn-gap switches is in terms of the two items of information most readily obtainable in system operating practice, namely the current to be interrupted by the switch and the voltage across the switch after opening. Because of the generalized character of the previous arc investigations, it seemed desirable to obtain data pertaining specifically to horn-gap switch operation by direct measurement of arc length, reach, current, and open-switch voltage, and to make a sufficient number of tests to provide a considerably larger

amount of data than was available from the previous tests.

All of the previous work having to do with arc dimensions was related to length and no information was developed relative to reach. As this is the more vital item in switch operation, it seemed especially important to develop data on this factor. It also seemed essential to further investigate how length of arc varied with the current because of the variable conclusions of the earlier work.

General Description of Tests

Tests were made at a frequency of 60 cycles and covered opening horn-gap switches under three general conditions:

1. Opening one side of a 33-kv transmission line loop and transferring its load to parallel paths.
2. Interrupting transformer exciting current at voltages from 12 to 49 kv.
3. Interrupting 132-kv line charging current, with and without gas blast.

Several types of switches were used: the tilting-insulator type with both conventional and quick break horns; the vertical-lift type; and the horizontal double-break type.

In addition, there was provided an arrangement called a swinging beam switch. It consisted of a pair of long horizontal swinging beams operated by ropes and fitted with insulators, contacts, and arcing horns. It was used to rapidly draw arcs out to wide openings in order to study this effect.

As experience soon indicated, arc breaking ability and length of arc were not appreciably affected by the type of switch, so most of the later tests were made with the vertical lift switch which placed the arcs in the best position for photographing.

Tests were generally made in groups of five with the same conditions maintained for each test in the group. Motion pictures were taken of the arcs with two cameras placed at right angles to provide means of obtaining arc dimensions. Oscillograms of arc current and arc voltage were obtained. Average wind velocity varied from about 2 to 20 miles per hour, but equipment was not available for measuring gusts during the actual arcing intervals.

Approximately 400 test openings of all types were made. These produced 273 free arcs suitable for analysis. Data from many tests could not be used because photographic results were unsatisfactory. The work included a number of tests with gas blast and expulsion interrupter devices. These results are not included in this paper as they are outside its scope.

Loop Current and Transformer Exciting Current Tests

Loop Current Test Procedure

A group of test switches was installed in the yard of a large substation and connected as shown in Figures 1 and 2 to interrupt one phase of a 33-kv line between the substation and a nearby generating station. This line was in parallel with an extensive system. During these single-phase test openings, no load was dropped as the current was simply transferred to other parallel paths. Various system arrangements provided different values of loop impedance. These, together with variations in generation, produced a wide range of current and open switch voltage. At this location 72 arcs suitable for analysis were obtained.

Another group of 48 tests was carried out on a 33-kv switch in normal service to obtain a comparison between arcs from 3-phase and single-phase openings at this location. A total of 81 arcs was obtained for measurement. This circuit is shown in Figure 3. A wide range of current and open switch voltage was obtained by phase angle and voltage control on a transformer in the transmission loop. The single-phase tests were obtained by making two phases of the switch inoperative. The loop opening test currents varied from 56 to 312 amperes with 1,000 to 7,600 volts across the open switch gap. The higher voltages were associated with the higher currents. Arcs as long as 25 feet were obtained.

Transformer Exciting Current Test Procedure

The transformer exciting current tests provided 72 free arcs. They were made with the test setup shown in Figure 4. Tests were made at voltages from 12 to 49 kv. Currents ranged up to 35 amperes, with arcs as long as 44 feet. The test switches, arranged for either single or gang operation, were used to obtain data with either single break, or with double break with both switches in series.

Analysis of Test Data

Figures 5 and 6 are views of typical loop and exciting current arcs enlarged from motion picture frames taken at the time of maximum arc length. The greater current in the case of the former is

Figure 3. Transmission loop used for single- and 3-phase openings

Figure 4. Test arrangement for opening transformer exciting current

seen to produce a much thicker arc. Figures 7 and 8 are typical oscillograms of loop and exciting current interruptions. They illustrate the decrease in current from initial value to zero and the corresponding increase in arc voltage from zero to open circuit value. In the case of the loop openings, the open circuit voltage across the switch depended mainly upon the current interrupted and the impedance of the loop. In the exciting current openings it was the line-to-neutral voltage.

The oscillograms were calibrated in terms of crest values divided by $\sqrt{2}$ to give rms on the assumption that wave shapes were sinusoidal. As they were often nonsinusoidal and peaked, some values used in the analysis were inherently higher than rms. However, since arc persistency is affected by crest rather than rms voltage,[3] the values used were considered satisfactory, as they were proportional to crest.

Arc reach and length were determined from the two corresponding projected motion picture frames showing maximum arc length. This generally occurred just before current interruption and arc extinction. The arcing interval was considered to end with the last frame showing a continuous arc. Actual current interruption may have taken place slightly earlier.[4]

It was originally thought that proper values could be obtained by considering the length as the square root of the sum of the squares of the lengths as traced from the two corresponding right angle views, as has been done by others.[3] However, it was found that this procedure could result in considerable error because: it does not take into account the upward incline of the camera lines of sight; the arc paths are often far from straight lines, and one dimension (vertical) is included in both views.

An improved procedure was adopted which, although not completely rigorous, largely overcame these errors. The method is explained in the Appendix.

Length and Reach for Exciting and Loop Current

The arc data actually involves three basic variables, namely, current, voltage, and length. The data were analyzed by using current at the beginning of the arcing period, voltage just after the arc was out, and length when the arc was longest. By taking advantage of the proportionality of arc voltage and length, the data on these two parameters were reduced to a single variable, feet per kilovolt, leaving current as the other variable. This reduction to two variables permitted all data to be shown with two co-ordinates and greatly aided plotting and study. The data on reach were handled in the same manner.

Length and reach per kilovolt are plotted against current in Figures 9 and 10 respectively. The ratio of reach to length is plotted in Figure 11. Each arc is represented by a separate point. Three-

Figure 8 (right). Representative oscillogram of exciting current interruption

phase openings produced three points.

The values of length and reach per kilovolt are widely spread. This spread is thought to be largely due to variation in atmospheric conditions, magnetic and thermal effects, and errors incident to accurately identifying the devious arc paths when tracing the photographic views.

It was observed that wind conditions greatly affected the shape of an arc and its direction but did not appreciably affect its length. With light wind it tended to be very irregular and circuitous. With strong wind it tended to be blown out horizontally windward, often like an elongated "V." Some of the longest arcs in several current and voltage groupings were obtained with very little wind but these were usually very circuitous. The more circuitous arcs usually had relatively less reach, which produced the low ratios shown in Figure 11.

In Figure 9, a curve has been drawn medially through the points to show the general trend of length per kilovolt with current. Above 120 amperes the trend is essentially flat and conforms fairly well with the EEI-Bell System Report.[3] Much effort failed to produce a mathematical expression that would satisfactorily fit the data throughout its range. Curves plotted from the formulas presented by Ackerman, and by Monseth and Robinson are shown. Ackerman's formula was obtained from data above 70 amperes and in that range the general direction of the curve follows the trend fairly well, but is lower. As his arc measurements were taken from single views low values of length are to be expected. The Monseth and Robinson curve is less similar. As their formula was presented in connection with relay studies, the data used for its derivation probably was obtained from larger currents. Neither curve fits the data in the lower current range. The trend curve levels off at 2.4 feet per kilovolt, equivalent to 417 volts per foot.

A trend curve for reach was similarly drawn in Figure 10, and its shape is about the same as that for length. As the limits of reach provide the vital dimensions in determining switch performance, the trend curve is only of general interest.

For reasonably safe operation, switches must have clearance greater than the probable reach that may be expected normally. It was thought that a simple upper limit above the highest test points would meet this requirement. Such a limit is provided in Figure 10, by a horizontal line at a height of 1.65 feet per kilovolt between 320 and 100 amperes, and below 100 amperes by a straight line dropping to zero with a slope of 0.0165 foot per kilovolt per ampere.

This limit line seems high in the lower range of current. However, the ratio of reach to length was generally lower in this range due to the circuitousness of these arcs. Consequently, because of the possibility of less circuitousness under some conditions, it seems reasonable in practice to use values somewhat higher than the test points. With these small currents, no switching problem exists unless they are associated with a relatively high voltage (line-to-neutral in the case of exciting current) and correspondingly long arcs. As reach per kilovolt from the curve is a multiplier, it seemed desirable that the curve be drawn to provide conservative values of reach when used with higher voltages.

Within the range of Figure 10, it is believed that reach per kilovolt as obtained in practice will rarely exceed values given by these limit lines which are accordingly identified as the limit of probable reach. The upper limits of probable reach can, therefore, be expressed simply as follows:

Range in Amperes	Probable Reach
0 to 100	$0.0165 \times kv \times I$
100 to 320	$1.65 \times kv$

Probable reach is in feet; kv is in rms kilovolts across the separated horns after opening; and I is the current interrupted in rms amperes. Reach on rare occasions under adverse conditions may approach one-half of the arc length and exceed the probable limit given by the foregoing expressions. If this maximum reach does occur, it must be in the general direction of switch alignment where clearance is usually ample. If the switch horns have any appreciable opening prior to arc extinction, the reach, if it occurs in a crosswise direction, is inherently somewhat shorter than that along the switch alignment as explained in the Appendix. Consequently, these expressions normally should be adequate for a design and operating guide. If a greater safety factor is desired, a ratio of one-half can be applied to the higher lengths points in Figure 9 and more conservative reach values obtained.

Comparison of Single-Phase and 3-Phase Openings

As stated previously, one group of loop tests was conducted with the loop shown

Figure 9. Arc length per kilovolt for resistive and inductive current

Figure 10. Arc reach per kilovolt for resistive and inductive current

in Figure 3 for the additional purpose of comparing the length and reach of single-phase openings with those of 3-phase. This comparison is shown in Figure 12. Bars in groups of three represent tests of three-phase openings and single bars represent single-phase openings. The length of the arc is represented by the total length of the bar and the reach by the open portion. It can immediately be seen that reach never exceeds half the length.

The voltage across a switch after opening only one phase should be greater than that after simultaneous 3-phase opening of the same current, because the impedance applicable to single-phase opening may be as much as $1^1/_2$ times the normal (positive sequence) 3-phase impedance. A correspondingly longer arc should result from opening only one phase. In this group of tests, the impedance for single-phase opening was calculated to be 10 per cent more than that for 3-phase, and the single-phase arcs should have been correspondingly longer.

The 3-phase openings are identified separately in Figures 9, 10, and 12. The effect of the theoretical 10 per cent overvoltage is not discernible. It was probably masked by the spread of the data. It can be seen that the points representing the 3-phase openings are well interspersed with those of the single-phase openings.

It might be expected that the first arc to go out would be longer than the other two because of the overvoltage effect with single-phase opening. From Figure 12 it is seen that there is no consistency in the order of extinction of any of the three arcs during 3-phase openings regardless of their individual lengths. Because the three arcs are concurrent and subject to 3-phase conditions during the major portion of the arcing time, the effect is probably minimized. However, in these particular tests any such differences would probably not be evident on account of the spread.

The duration bars show, in addition to the duration of each arc, the times of initiation and extinction as determined from the motion pictures. The arcs of greater duration generally have longer length.

The variation in time of initiation of the arcs is of some interest. As the test switch had been checked for good adjustment, this variation in timing and contact separation is probably typical.

The bars showing arc terminal separation represent the separation between the ends of the arcs on the horns at the time of extinction. The arcs often went out before they had traveled to the horn ends and before full opening. The arc terminal separation was usually greater with the longer arcs. It is to be observed that greater separation occurred in the case of single-phase openings than with 3-phase, with the arc durations generally shorter and the length no longer. For the single-phase openings, the switch mechanism was disconnected from two of the phases. This resulted in faster switch operation and apparently shortened the time required for the arc to attain the critical length needed.

Other Observations

There were no consistent differences in reach and length of arcs drawn on different switches.

The tests with the swinging beam switch when rapidly opened and a few with "quick break" horns on a tilting insulator switch showed that the arcs were not shortened by their use. The quick separation caused the arc to follow a fairly straight path between terminals until maximum opening was attained (about 15 cycles of time), after which it expanded in a normal manner until critical length was attained. Short arcs were out before full opening was attained. With the wider opening, reach in a crosswise direction was less for the longer arcs even though they continued to grow after full opening. This latter feature might be made helpful in confining an arc to space within clearance limits.

With wind parallel to the switch alignment, one side of the arc loop may be blown directly across to the opposite horn. This short circuits the arc and prevents or delays its extinction. A long horn away from the wind increases the susceptibility to this effect, as the arc would tend to rise against it.

Occasionally the wriggles of a portion of the arc short circuited. This shortened the arc and caused the arc loop to start growth anew. In these cases the oscillograms showed an abrupt increase of current during a normally decreasing trend. This effect generally increased the time required for extinction.

The double break switch used for some of the loop opening tests and the two switches used during the exciting current tests yielded information on two arcs in series. The lengths of the two arcs in series, when added, approximated the length of a single arc under the same conditions. However, one arc of the pair was sometimes as much as four times as long as the other.

There has thus far been no reference to the effect of power factor of the current in the circuit opened. Tests by others have shown that in resistive and inductive circuits there is no difference in persistency of arcs formed.[2] Our tests have confirmed this point as no differences were discernible with variation of circuit power factor in either the loop or exciting current tests. Opening of line charging current is a separate matter as discussed later.

Tests with arc quenching arrangements demonstrated that both properly directed gas blast and expulsion interrupter de-

Figure 11 (above). Ratio of reach to length

vices have merit for extinguishing horn-gap switch arcs.

Tests at 132 Kv—Loop and Charging Current Opening

132-Kv Line Test Procedure

Tests were performed on 132-kv horn-gap line sectionalizing switches to determine lengths of line that could be safely de-energized. In all cases, motion pictures of the arcs and in a few cases oscillograms were taken. Current values, in most cases, were calculated from the line characteristics and the prevailing voltage.

Of 25 openings, nine provided 27 free arcs suitable for measurement. In these tests, various lengths of line ranging from about 4 to 50 miles were opened. Currents ranged from 2.2 to 20 amperes.

Nine tests were made with gas blast attachments for quenching the arcs. These attachments consist of porcelain tubes mounted on the switch bases through which gas is discharged toward the short stationary horn on which the arc is initiated. The gas was supplied from nitrogen tanks on the ground used to charge auxiliary tanks mounted under each of the three switch bases. Nitrogen at 115 pounds per square inch was discharged by quick opening valves operated from the switch mechanism. Air at 90 pounds per square inch also was used experimentally. These 27 arcs were all measurable.

132-Kv Line Test Results

The length and reach data from these tests are plotted in Figure 13 which includes a comparison with the lower portion of the reach and the length trend curves for resistive and inductive currents from Figure 10. The reach and length per kilovolt were determined by using voltage-to-neutral at the time of the tests and current values either calculated or obtained from oscillograms. It will be noted that both reach and length per kilovolt are generally higher for line charging current than for resistive and inductive current of comparable value. This result is to be expected because of the trapped charge and stored energy in a capacitive circuit which tend to create higher arc voltage and a longer arc before extinction. Tests by other investigators have shown that restriking of long arcs following extinction at current zero occurs only in a capacitive circuit and that the open circuit voltage rises to approximately twice normal.[8]

Figure 14 is a bar chart similar to Figure 12, summarizing the data for the 132-kv line tests.

Currents up to seven amperes were interrupted with reaches which appeared safe for the horizontal phase spacing of 16 feet. Currents of 10, 13, and 20 amperes were also interrupted although resulting reaches were greater than the phase spacing. The favorable oblique wind was responsible for the success of these openings since arc lengths ranged up to

Figure 13. Arc reach and length per kilovolt for 132-kv line charging current

123 feet and arc reaches ranged up to 25 feet. Figure 15 is an enlargement of one of the motion picture views of a 20-ampere opening.

The results of gas blast arc included in

Figure 14 (left). Reach, length, terminal separation and duration of arcs for 132-kv line charging current

Figure 15 (above). Opening 20 amperes of charging current on a 50-mile 132-kv line, length 123 feet, reach 20 feet, switch clearance 16 feet

Figure 14. The effectiveness of this method is demonstrated in this figure by comparison of the data for the 7-, 13-, and 20-ampere line charging current openings with and without the blast. The 100-, 142-, and 149-ampere data with gas blast were obtained in opening one side of a 61-mile double-circuit loop, totaling 122 circuit miles.

Application to Practice

The most practical criterion for adequate switch clearance is "reach". The distance that an arc may reach from the switch provides a basis for determining the clearances necessary for safe operation. The probable limits of reach previously derived and shown in Figure 10 may be used for estimating horn-gap switch interrupting ability.

Reach for Resistive and Inductive Currents

Where the currents are associated with resistive or inductive load and are less than 100 amperes, reach may be considered to be 0.0165 foot per kilovolt per ampere. The maximum reach expected can then be determined by multiplying this value by both the current and the voltage across the open switch gap.

Where the currents are between 100 and 320 amperes, the maximum reach may be considered as 1.65 feet per kilovolt. The maximum reach expected in this case can then be determined by multiplying this value by the voltage across the open switch gap.

Maximum arc reach for opening exciting current of 3-phase transformer banks at various line voltages in common use, based on a factor of 0.0165 foot per kilovolt per ampere, is shown in Figure 16. The curves are for nominal line-to-line voltages but have been calculated on the basis of line-to-neutral voltages which actually apply.

For opening a switch in a loop circuit, a satisfactory value of voltage usually can be obtained simply by multiplying the current through the switch by the equivalent impedance of the loop opened. This impedance can be determined by simple vector additions of the component impedances in the loop. In the unusual case of opening one phase only, impedances must be determined accordingly. If transformers are in the loop, their impedances and ratios must be taken into account. The refinement of taking synchronous machine and load impedances into account does not appear to be normally necessary.

The loop impedances applicable to opening a horn-gap switch in any line often may be predetermined from measurement of voltage and current at an oil switch elsewhere in that line. The voltage across the gap obtained with the oil switch open, divided by the current just prior to opening will give the impedance of the loop regardless of line load at the time of measurement.

After the equivalent loop impedance has been obtained (either calculated or measured), reach can be determined directly from Figure 17 for currents over 100 amperes. This figure shows arc reach for current interrupted with various loop impedances. It is based on the expression, reach equals 1.65xkv, with $IZ/1{,}000$ substituted for kv. For currents less than 100 amperes a chart could be similarly constructed by the same substitution in the expression, reach equals 0.0165 x kv x I.

This basis of estimating the capability of a horn-gap switch is applicable to any loop circuit regardless of operating voltage, as the latter has no particular relationship to the gap voltage.

Switch Design and Operation

For design, or to ascertain if a switch may be safely opened, the expected arc reach should be compared with the proposed or actual switch clearances. The general type and arrangement of some commonly used 33-kv switches is shown in Figure 18. The minimum clearances between phases are shown in Table I. To avoid short circuit, a margin of safety is needed between maximum expected reach and the actual minimum clearance. The amount is largely a matter of judgement. A margin of one foot is believed satisfactory for 33-kv switches under ordinary conditions. Maximum safe reach providing a 1-foot margin also is shown in Table I.

As a convenient operating guide, the horizontal lines in Figure 17 show the maximum safe reaches for the switches in

Figure 16. Arc reach for small currents at various line voltages

Figure 17. Arc reach for large loop currents in loops with various impedances

Table I. With favorable wind directions, longer reaches may be allowed.

Examples of Reach Determination

Example 1—Interrupting Transformer Exciting Current. A 15,000-kva 132-kv transformer is to be replaced by one of 30,000-kva capacity. The existing horn-gap switch for interrupting the exciting current is of the vertical-lift type with 10.5-feet horizontal separation between phases. It is desired to know whether this switch will have adequate clearance to interrupt the exciting current of the larger transformer. Test data on the proposed transformer gives 2.0 per cent exciting current at rated voltage and 9.0 per cent at 110 per cent rated voltage. It is expected that the line voltage will be 132 kv but that the transformer taps will be set 5 per cent below rating, thus over-exciting the transformer 5 per cent. It is estimated that the exciting current will be 4.5 per cent, or 5.9 amperes. Referring to Figure 16, it is seen that interruption of 5.9 amperes at 132-kv line voltage gives an arc reach of 7.4 feet. This is 3.1 feet less than switch clearance of 10.5 feet. Therefore, the switch should be adequate.

If it is expected that the line voltage may vary from 132 kv, the exciting current should be determined accordingly and the reach obtained from the formula in Figure 16.

Example 2—Opening a Transmission Loop. It was desired to determine if flashover would occur on a horn-gap switch in sectionalizing a line in a 33-kv loop when the current was 200 amperes. The switch had clearance of 4 feet 8 inches (switch arrangement (A) in Table I). Loop impedance was determined by measurement at one terminal of the line. Potential transformers used for synchronizing were available on both sides of the line oil switch. By connecting a voltmeter across the appropriate terminals of the synchroscope, the voltage across the oil switch gap could be measured.

With the oil switch closed the current was 250 amperes. With it open the voltage across the gap was 5,000 volts. The loop impedance was, therefore, 20 ohms. Referring to the "X" in Figure 17, it was seen that interruption of a 20-ohm loop at the expected 200 amperes would have given an arc reach of 6.6 feet. This was above the allowable reach line, designated as Figure 18(A), for this switch. Therefore, opening the horn-gap switch was considered unsafe. The diagram shows that the switch could have been opened safely if the current were not over 142 amperes.

In this example, 5,000 volts was observed across the oil switch gap. This might be considered excessive but it was the vector difference and not the scaler difference between the line-to-neutral voltages on each side of the switch. The line voltages were respectively 34,000 and 31,000 volts.

Had it not been convenient to measure the voltage as described, the impedance of the loop would have been determined by network reduction from line and transformer constants.

132-Kv Line Charging Currents

The 132-kv line charging current tests have demonstrated that about seven amperes, corresponding to charging current of 17 miles of line, may be safely interrupted. This value of current results in arcs having reach shorter than the horizontal phase spacing of 16 feet. The tests demonstrated, however, that under favorable wind direction charging current as high as 20 amperes could be interrupted.

Figure 18 (below). Horn-gap switch arrangements

Figure 19 (right). Adapting camera views for measurement

Conclusions

General

1. An open arc formed on adequately separated electrodes will go out if it is free to expand to its critical length.

2. A horn-gap switch will successfully interrupt a current if its dimensions are adequate to permit the arc to grow to its critical length. An exception might be with the wind blowing in line with the arcing horns.

3. With conventional horn-gap switches, arc length and reach are independent of the type of switch and of the speed of operation.

4. Two arcs in series have about the same total length as a single arc produced under the same conditions. One of the pair may be much longer than the other.

5. Arcs are longer when interrupting line charging current than when interrupting a corresponding amount of resistive or inductive current with similar voltage across the switch gap.

Application to Resistive and Inductive Current.

6. Reach for currents below 100 amperes depends on both voltage and current. Maximum reach for practical use in this range is 0.0165 foot per ampere per kilovolt across the open switch gap.

7. Reach for currents from 100 to 320 amperes is proportional to voltage but independent of current magnitude. Maximum reach for practical use in this range is 1.65 feet per kilovolt across the open switch gap.

Application to 132-kv Line Charging Current

8. On 132-kv horn-gap switches having 16 feet separation horizontally between phases, about seven amperes of charging current (approximately 17 miles of line) can be opened with reasonable safety. Larger currents up to 20 amperes can be interrupted if wind direction is favorable.

Table I. Relation Between Clearance and Safe Reach for 33-Kv Switch Mounting Arrangements of Figure 18

Switch	Arrangement Description	Minimum Clearance Between Phases: Path	Minimum Clearance Between Phases: Distance	Allowable Safe Arc Reach
A	Tilting-insulator type, two level mounting. Length of stationary horn, 1'3". Length of movable horn, 1'3". Applies only when bases are not grounded	Between open horns of lower switch and line clamp on moving contact end of upper switch. (Involves the two phases located on same side of pole)	5'8"	4'8"
B	Vertical-lift and tilting-insulator types, all phases on same level. Applies with bases grounded or not grounded	Between open horns of adjacent switches	4'7"	3'7"
C	Double break, horizontal opening, all phases on same level. Blade radius 1'8". Applies with bases grounded or not grounded	Between stationary horn of one switch and horn of open blade of adjacent switch with simultaneous arcs on adjacent switches	4'1"	3'1"

Appendix

Measurement of Arc Reach and Length

Motion pictures are equivalent to projections from single points on planes perpendicular to the inclined lines of sight from the cameras as shown in Figure 19(A). In this figure the arc is indicated behind the projections on the view planes. The projections for extreme accuracy should be orthogonal; but, of course, that is impossible with photography. The shaded plane in this figure passes through both cameras and the base of the arc. These three planes are, for practical purposes, at right angles to each other and are used for determining arc dimensions. The intersection line OZ of the view planes is taken as the Z axis, and the other intersection lines OX and OY are taken as the X and Y axes respectively.

With these axes, arc dimensions in the direction of Z are the same in both views. If the two view planes as shown in Figure 19(B) are rotated into a common plane about line OZ, they appear to be tipped downward by approximately the incline angle of the cameras as shown in Figure 19(C). In this rotation, the X and Y axes fall into the same straight line which is perpendicular to OZ. A method based on this rotation was used in adjusting the views for measurement.

In the actual procedure, the two views were projected on a screen, side by side, by similar motion picture projectors. The machines were each stopped at maximum arc length and their positions adjusted to give the same scale to the two pictures. The known diameter of an insulator in the switch base was usually used to set the scale. The two views were then traced on separate sheets of paper, with one arc terminal encircled on each trace for identification. Prior to measurement, the traces were rotated as shown in Figure 19(C) so that corresponding terminals and the uppermost part of the arc were on horizontal lines. This adjustment was equivalent to rotation about the OZ axis.

The reach was first determined and the axes were drawn on each trace as shown, with the origin midway between arc terminals. Corresponding points have the same height on both traces and must be on the same side of the arc. Reach is the maximum straight line distance from the origin to any point in the arc as shown by line OR in Figure 19(C). It was determined by trial from the two traces to give the maximum value of $\sqrt{x^2+y^2+z^2}$. Trial points were at the same height on both traces and on the same side of the arc. In the actual arc, the reach point is usually uppermost, but due to camera incline it may not necessarily be so on the traces.

From these generally irregularly shaped traces, the most accurate method of measuring total length would be to divide the traces into segments, determine the length of each $\sqrt{dx^2+dy^2+dz^2}$, and then take the sum. It was found that acceptable accuracy was attained, however, by dividing the arc at R and measuring each side separately.

Referring to the YZ trace in Figure 19(C), the distance from A to R was measured with a tracing wheel by following the curvature and wriggles of the path. The distance D_{yz} was considered as $\sqrt{y^2+z^2}$. The x dimension was the horizontal distance between points A and R on the XZ trace. The actual distance between A and R is determined by the relationship $\sqrt{D^2_{yz}+x^2}$. A similar measurement was made of the same side by using the tracing wheel along the line from A to R in the XZ trace and obtaining y from the other. A length $\sqrt{D^2_{xz}+y^2}$ was thus obtained and the value used for the length of the side AR was taken as the average of the two. The other side of the arc from B to R was similarly measured and AR and BR added to give the total length.

In most cases, particularly those having a wide open path, the reach was considerably less than half the length. Occasionally, probably due to more wind velocity, the arc sides were nearly straight and gave ratios of reach to length of nearly one half.

Locus of Maximum Reach Points

Assuming the extreme case for a given arc length where the path has no wriggles and consists of two straight lines from the electrodes to the point of reach, it can readily be seen that the locus of reach points is an ellipsoid. The arc terminals are the foci of the ellipsoid and its long axis equals the arc length. Reach along this axis would be one-half the length if the arc were not interfered with by the intervening horn. That ratio can nearly be attained, however, with reach in the general direction of the long axis. Reach will, in a crosswise direction, be somewhat less by an amount which depends on the spread of the foci or arc terminals. As there is generally less clearance in the crosswise direction, a quick wide spread of arc terminals is beneficial. High speed of separation is necessary, however, if the wide spread is to be effective in reducing the crosswise component of reach.

Discussion

H. A. Glover (Electrical Engineers Equipment Company, Melrose Park, Ill.): This paper shows a job of tremendous proportion well done. A well-deserved compliment is extended to the authors and to the Public Service Company of Northern Illinois for the performance of the tests and the thorough and complete paper prepared.

This is the first real guide as to what a horn-gap air-break switch can be expected to do. It is probably the first time formulas, curves, and other data on this subject have been made available to engineers. Since data of this type has never been accumulated previously and uncontrollable factors prevent assigning any guaranteed interrupting ratings to horn-gap switches, this paper should become a part of every substation and overhead line engineer's library.

From the paper it is noted that variations in wind affected arc reach, but not length. Did tests give any indication of effect of temperature or other atmospheric conditions?

Also, some questions in switch design are indicated by these tests, as:

Would a horn-gap switch with extremely long break result in arc of even smaller reach, or could this effect be attained more readily by increased speed of opening, as indicated in tests on single-phase circuits with mechanisms of two poles disconnected?

Can the tests be considered to indicate that a double-break switch, with two arcs in series, would assist in a design to reduce reach of the arc? This would depend on what the reach of the longer of the two arcs in series measured, in comparison to single-break design switches.

Would switch design with contacts and blade tips modified to provide a sphere gap effect in opening be possible, thus eliminating horn? The design would have to prevent burning of main contact points. This appears to have some possibility since photographs indicate horns are not actually required as guides for the arc.

In conclusion, it can be repeated that the paper is complete and should be extremely useful. Certainly, there is no question that little was overlooked in preparing for this study and in the actual carrying out of the tests and preparation of the paper.

G. E. Heberlein (Railway and Industrial Engineering Company, Greensburg, Pa.): This paper raises a question which has been the subject of much discussion among operating people. Let us review the early record and background.

The early expansion of the a-c system was augmented by the introduction of horn-gap switching of load and charging currents. Forty years ago, the Railway and Industrial Engineering Company introduced the air-break switch placed upright, outdoors, and arranged to open the arc, using increased clearances and phase spacing over that needed for a regular isolating hook switch. The arc was severed on horns projected upward and outward and designed to interrupt the arc where no damage could result. Today it hardly seems possible that the first stations were indoor type and the introduction of the air-break switch forced the use of outdoor construction before that construction was dictated by the greater space requirements of higher voltages.

Many thousands of these switches were installed all over the country because operators could not afford the higher cost of circuit breakers for the expected return on investment. While the circuits in the aggregate then were not long, and load and charging currents more limited, yet the air-break switch did its work and is still today the accepted method of switching of many overhead lines.

True, under unfavorable conditions as to winds and loading, they failed to open the arc and in some cases initiated faults. In these cases, the backup circuit breaker cleared the fault, was then again closed, restoring service to the line section. Today there are still thousands of these switching installations in use, sectionalizing, or picking up, or dropping lines or load—the economic answer to the individual problem.

The material presented in the paper should prove of considerable value as a practical guide to system switching with horn-gap switches.

Our companies in the United States and Canada have accumulated records of operating experience gathered through the years. These record the practical experience of operating companies in opening circuits of various voltages and currents with switches of both standard and special types and spacings. This material could not be systematically collated as has been done by the authors as no criteria of agreement between these data could be developed.

From a very general analysis of this background, we have advanced the following recommended practice of operating with horn-gap switches. Each particular case should be analyzed on its own merits evaluating:

1. Current, voltage, and frequency.

2. Atmospheric conditions, that is, prevailing winds.

Figure 1. 115-kv 11-ampere charging current on 16-foot phase spacing. Wind 5 miles per hour

Figure 2. 66-kv 11-ampere charging current on 16-foot phase spacing. Wind about 8 miles per hour

3. Installation conditions (mounting space and the cost of special switch provisions).

As a very rough guide, the standard horn-gap switch at conventional spacing, either of the vertical or horizontal opening type, can be used for successfully breaking up to 5 amperes of line charging current.

For currents in excess of 5 amperes, we recommend the use of switches with a greater tip-to-tip gap when in the fully open position, and greater than normal phase spacing, the basic problem being how much space must be placed between arcing horns to prevent the arc from being carried into the arc terminals of the next phase under the influence of low-velocity cross-phase winds. As borne out by the paper, high-velocity winds cool the arc quickly, while winds of three to six miles per hour carry an arc, thus limiting the amount of charging current successfully handled. For example, a double-rotating side-break switch arranged for 110-degree rotation (rather than 90 degrees) at 132 kv will create an open gap of 8 feet 6 inches when fully open, and will handle up to 9 or 10 amperes on 15-foot phase centers. Mounted on 20-foot phase centers, it could be used up to about 14 amperes charging current.

The striking difference between opening magnetizing and charging current can be seen on Figures 1, 2, and 3 of the discussion, and also illustrates the difficulty of correlating the usual data obtained from various investigators as it is impossible to specify the "reach" in these three cases. The difference in "arc laziness" is easily seen, as well as the effect of the stronger winds.

The authors make no distinction between

Figure 3. 230-kv 5.7-ampere magnetizing current at 25 cycles (two phases already extinguished). Wind 15 miles per hour

standard horn-gap switches. Substantially there is no great distinction but we have found construction factors do influence interrupting ability. For instance, copper horns or copper-clad horns interrupt better than aluminum or galvanized horns. Likewise, on loop circuits in transfer of load with relatively high current at low voltage (under 10 kv), Elkonite arcing tips perform better than copper or copper alloy, permitting the interruption of much higher currents than otherwise possible.

Special switch designs are available with increased open gap clearances. These switches of the 2-insulator double-rotating variety, center break, horizontal opening to 110 degrees or 180 degrees, can give open gap clearances approaching double that of the conventional switch at practically no increase in investment cost. For example, in one group of tests, a special switch of this type opened load currents up to 2,000 amperes at 25 kv.

In Table I of this discussion are examples of interruption with standard side break switches with and without transformer termination.

Table I

Voltage of Line, Kv	Length, Miles	Condition	Length of Arc, Inches	Time of Arcing
44	7	Line open	2	Instantaneous
44	12	Line open	4	Instantaneous
44	31	Line open	12	1/8-second
44	31	3,000-kva transformer unloaded	3	Instantaneous
44	31	6,000-kva transformer unloaded	2	Instantaneous

Concluding, the authors should be commended for their presentation of means to more carefully evaluate operating practice using horn-gap switch interruption. Power companies will undoubtedly use their methods to more rationally evaluate load and charging current interruption, thereby limiting the need for more expensive equipment such as interrupter switches or circuit breakers.

C. S. Beattie and **S. C. Killian** (Delta-Star Electric Company, Chicago, Ill.): For many years there has been a definite need for some means of estimating the interrupting ability of an air switch. This paper provides a bench mark and a quick answer to a question that has been raised over and over again by the users of these switches. The authors are to be congratulated for their fine paper and should be thanked for the enormous amount of time spent on field tests, arc measurements, and calculations. We had the privilege of witnessing some of the tests and can vouch for the carefulness and exactness with which tests and measurements were made.

Two major results are reported. The first covers the relationship between the switch and the arc and states that the interrupting ability of a switch is not determined by the construction of the switch or by its speed of operation. The other result states the importance of arc reach and provides a formula for estimating it. It is of interest to transpose the authors' formula for reach at lower currents into

$$I = \frac{\text{reach in feet}}{0.0165\,\dfrac{\text{KV}}{\sqrt{3}}} \text{ amperes}$$

where KV = line to line voltage

Then, by substituting standard phase spacing for horn-gap switches given in Rule SG8-57.5 of the National Electrical Manufacturers' Association Power Switching Equipment Standards,[1] for the reach, some value of current can be determined which a horn-gap switch should break with fair surety. The authors prefer to add an additional foot to the phase spacing at 33 kv as a safety factor and likely more at high voltages but this is open to debate since the arc would have to lay down in an almost horizontal position in order to fault between phases if the reach were equal to the phase spacing. Table II of this dicussion gives inductive and loop currents which can be interrupted using equation 1 with the reach equal to NEMA phase spacing. There is startling agreement with the rule-of-thumb interrupting value of 10 amperes for standard conditions of switch mounting at higher voltages. This value of 10 amperes has been used by us for years on the basis of inconclusive tests. It also is important to note that contrary to general thinking, the size of the open switch gap does not effect the interrupting ability unless very large changes are made. Rather than widen this open gap on each switch unit, it would be more preferable to add to phase spacing.

It will be interesting to compare the authors' results with those of a nation-wide utility poll being conducted by an existing AIEE subcommittee, questioning each utility company's practice in using air switches as interrupting devices. Early poll results indicate somewhat lower values than those given in Table II of the discussion though agreement is not too bad.

Figure 14 of the paper illustrates the efficiency of the gas-blast type of interrupter as added to an air switch. As further improvements are made on this device, a considerably wider field may be opened for its use, especially in voltages above 69 kv.

1. POWER SWITCHING EQUIPMENT STANDARD. *Publication 49-144*, National Electrical Manufacturers Association (New York, N. Y.), April 1949.

C. J. Beller (Cleveland Electric Illuminating Company, Cleveland, Ohio): Analysis of photographic records of horn-gap switch openings has provided much previously unknown information on the arc behavior. There is considerable evidence to indicate that safe opening of conventional horn-gap switches is limited to relatively low values of charging current and load current.

Tests of our own were recently conducted to establish conditions for the safe operation of horn-gap switches on our 132-kv system. These tests indicate that 2 amperes of 132-kv charging current or 4 amperes of 132-kv transformer exciting current, can safely be interrupted with horn-gap switches under adverse weather conditions.

Mr. Andrews and his associates have opened a door to the investigation of this problem and further study and test will greatly assist in arriving at some factual basis for determining limits of present installations and point the way to further development of better circuit opening devices for use on the higher transmission voltages.

Outdoor color film in better quality movie and still cameras gives a much better photographic record of switch opening arcs than can be obtained with black and white film. Exposures of 1/100 to 1/120 second with lens opening F-1.5 to 2.0 give very good pictures with daylight color film when photographs are taken against early evening north sky. Motion-picture cameras operating at 64 frames per second provide an ideal media for recording switch opening arcs. With this speed, counting of the frames measures the arc time, approximately 1 cycle per frame being recorded.

Eric T. B. Gross (Illinois Institute of Technology, Chicago, Ill): The extensive tests made on the systems of the Public

Service Company of Northern Illinois are of great value to the industry since the problem of arc interruption with disconnecting switches is economically important. This is one of the few publications on this subject. However, many interesting papers are available on free burning arcs. These arcs do not differ fundamentally from those made by the authors though the studies referred to were made for various other purposes, such as: the study of flashovers on insulators produced by overvoltages; destructive effects of free burning arcs on electric equipment, particularly insulators; effect of arc impedance on various types of distance relays; and possibility of self-extinction of arc faults.

Many of the results obtained from these other investigations are directly applicable to the problem investigated by the authors. Reference 2 of the paper is really based on unpublished investigations of A. R. van C. Warrington,[1] who published an early paper on the subject in this country.[2] Other investigations, also based on extensive tests,[3] deal with an analysis of arc voltage and current, and throw light on the power factor of the arc. An interesting investigation concerning arcs with the current nearly in complete quadrature with the voltage also may be mentioned.[4]

The problem of interruption of the magnetizing current of transformers seems to deserve particular consideration. If capacitances are in parallel with the transformer, arc interruption may become easier if the frequency of the circuit formed by the elements to be switched off is near the impressed system frequency of 60 cycles. The problem is then similar to the self extinction of arcing grounds in resonant grounded systems, since the voltage across the former path of the arc starts slowly from zero at arc interruption and permits complete de-ionization without restrikes which otherwise influence the arc duration. It would be of interest to learn if the authors observed the presence of such conditions during the tests.

P. A. Abetti (General Electric Company, Pittsfield, Mass.): The authors are to be commended for a long and thorough investigation of a problem of practical importance which has been heretofore almost neglected in the literature.

It appears that the main difficulty in reaching a definite formula of arc length versus voltage and current, which would be very useful for theoretical studies and practical applications, lies in the great spread of the test values. This spread appears to be due essentially to random errors, and may therefore be reduced by increasing the number of tests.

Once the variance and mean error of the tests have been established by statistical analysis, one can predict the probability that the reach will be larger than a given value, and, therefore, that a short circuit will occur for a certain switch. The authors have given in Figure 10 of the paper the "limit of probable reach," based empirically on the highest values obtained in their investigation of 225 arcs of resistive or inductive current. From this data it would be interesting to compute statistically:

1. The mean error of all tests.

2. The probability that the "limit of probable reach" will be exceeded, and that this limit plus a given margin, say one foot, will be exceeded.

Once the probability is known, it will be easy to ascertain whether one is willing to take that chance of a short circuit upon opening a certain switch, compared to the advantages which will result from such an operation.

The same considerations can be applied, with less confidence, because the number of tests is smaller, to the interruption of line charging current.

F. E. Andrews, L. R. Janes, and M. A. Andersson: Mr. Glover inquires about any indication of effect of temperature or other atmospheric conditions. There was no discernible effect from atmospheric conditions other than variations in wind. The variations in results indicated by the spread of the data in Figures 9 and 10 includes variations that may have been due to differences in atmospheric conditions. These, of course, could not be segregated from other factors causing variations.

Mr. Heberline states that he has found that copper or copper-clad horns interrupt better than aluminum or galvanized horns. Both copper-covered steel and galvanized horns were used in our tests. There was no discernible difference in their action. If there was any difference, it was apparently less than the spread due to other factors. Elkonite is also mentioned as permitting the interruption of higher currents. The effect of different metals used for arcing electrodes could well stand investigation in connection with application to horn-gap switches. This is one of the items which it would be desirable to include in additional tests under laboratory controlled conditions. Such tests, if made, should be conducted indoors free from the influence of natural wind but with an air stream well controlled with respect to both direction and velocity.

Certain design questions have been raised by Messrs. Glover and Heberline:

1. *The effect of a long switch gap*—It appears that a long switch gap would be beneficial if the opening could be fast enough to prevent a long reach in the critical direction.
2. *Double break with two arcs in series*—The tests made with two arcs in series indicate in some instances that the longer of the two arcs was as much as 80 per cent of the total length. It is the authors' opinion that there is no practical advantage from a double-break switch.
3. *A design to eliminate arcing horns*—As pointed out in the paper, arcing horns in themselves are of no particular benefit in interrupting the arc. Depending upon the switch mounting arrangement, long horns may lessen the critical clearance available for the reach. This is particularly true where a switch has more than one level. In such a case a design without horns or with very short horns would seem to be advantageous.

The analysis of NEMA phase spacing given by S. C. Killian and C. S. Beattie is very interesting. It is hoped that our work may be of value in further horn-gap switch standardization work.

We are glad to have the suggestions by Mr. Beller regarding the technique of arc photography as good quality of photographic work is important in arc studies.

Dr. Gross mentions the question of capacitors in parallel with the transformer to give a circuit having a natural frequency of about 60 cycles.

On a 60-cycle system this amounts to neutralizing the exciting current. No tests of this kind were made. However, our company has been using capacitors in connection with induction regulators for the purpose of offsetting most of their exciting current. This has permitted the use of smaller disconnect switches.

Mr. Abetti calls attention to the problem of establishing a definite relationship of length, current, and voltage because of the great spread of the test values. He suggests that this spread is due to random errors which could be reduced by increasing the number of tests. We consider that the wide spread is due to random variations rather than errors. These variations are probably due to conditions not susceptible to analysis by our methods. While a statistical analysis as suggested by Mr. Abetti would be interesting to evaluate the probabilities and some benefit might be obtained in this direction by a larger number of tests, we believe the greater need is for further investigation of the factors causing the wide variations.

We appreciate the interest as shown by the discussions and hope that further research will be forthcoming.

A Low Noise and Distortion Audio Multiplexing Equipment with High Stability Carrier Supply

F. S. BEALE
ASSOCIATE AIEE

THE equipment described in this paper was the result of conclusions reached while contemplating the problem of how best to utilize the 30-kc audio spectrum offered by the type *FB* microwave-radio equipment. The market for the radio equipment primarily was to be in the electrical utility field. It was proposed as suitable especially for providing telephone, telemetering, load-frequency control, supervisory control, and similar communication circuits over distances up to about 50 miles. It was recognized that with microwave radio, the terrain would be a control factor in the maximum length of a radio circuit without repeater stations. A need exists for a communication facility of multicircuit capacity for such distances, both because of the growing congestion of the power-line carrier frequency spectrum and because of the increasing difficulty of applying carrier to the shorter power lines.

Outstanding conclusions drawn from the study of this problem were the following:

1. Most electrical utilities are forced to provide communication facilities for themselves by the urgency of their emergency communication problem.

2. It has been unusual for them to hire experienced communications engineers and maintenance personnel, or to set up a communications staff. Often persons normally assigned to protective relaying activities have the communications problems added to their work load.

3. While the communication facilities are vital they often do not receive the benefit of well-planned and diligently prosecuted maintenance merited by the investment they serve.

4. The equipment is placed frequently in dusty locations, and practically is never air-conditioned.

5. Some equipment is located in outdoor shelters with no heat except where experience dictates use of some minimum amount of heat.

6. Of those applications where microwave radio can be applied, probably not over 5 per cent will require more than seven voice circuits, or 140 telegraph circuits, or intermediate combinations thereof.

7. Simplicity of technique should be the keynote in the multiplexing equipment design.

8. Complicated adjustments, and frequent readjustments, particularly, of multiplexing carrier frequencies, must be minimized or completely eliminated.[1,2]

9. Vacuum tubes should be used sparingly, conservatively, and should be selected from readily available standard types. No tube type which appears to have an uncertain future should be selected.

10. Variety of vacuum-tube types should be kept to a minimum.

11. Where possible, tube types should be selected from the list of those having industrial counterparts–the "ruggedized" tubes.

12. Building block design necessary to permit adaptability to the greatest variety of problems.

13. It must be mechanically designed to be assembled within an equipment cabinet, yet have a high degree of accessibility to tubes and parts for inspection and maintenance when required.

14. The equipment cabinet design and finish to be compatible with power plant and substation switchgear housings.

15. Standard equipment now in use for multiplexing wire facilities may be in use on some customer's property. To offer the same general type of equipment with the radio will fit into existing maintenance practices more readily.

The two fundamental methods of multiplexing a given communication circuit are frequency division and time division. Frequency division permits all circuits derived by this means to function simultaneously. The useful frequency range of the communication circuit which is to be multiplexed is divided into several frequency bands, each wide enough for handling the function or functions required of it. For telephone service the usual bandwidth is about 2,500 cycles per second—(from 250 to 2,750 cycles) and for a telegraphic service the bandwidth required is a function of the repetition rate of the pulses, and the maximum rise time (steepness of wave front and trailing edges) that can be tolerated by the service. Most telegraphic services can be handled in a 120-cycle bandwidth. The simplest of this form of multiplexing consists of a number of audio oscillators. Each is adjusted to produce a different frequency, and is connected to a common output circuit with all the others. When each is controlled by independent keying devices, we can have a telegraphic circuit and each can transfer information to its respective receiving device independent of the others. The rate at which such information can be transferred depends directly upon the previously-mentioned bandwidth, and therefore is limited by the design for the system.

Since it is not practical to adjust the frequencies of the voices of several people who might want to talk over a multiplexed circuit, to the different frequencies that would permit them to talk simultaneously over this circuit, without mutual interference, it becomes necessary to translate the signals of every but one voice to different parts of the spectrum of the circuit. By the use of well-known methods, several different carrier frequencies are used with individual provi-

Paper 50-162, recommended by the AIEE Carrier Current Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 15, 1950; made available for printing April 18, 1950.

F. S. Beale is with the Westinghouse Electric Corporation, Baltimore, Md.

Figure 1. Carrier frequency assignments, spacings, and voice circuit bandwidths for a typical frequency division multiplexing system which will provide reasonably complete utilization of a nominal 30-kc common circuit, whether wire or radio

sions for modulation, each being assigned to handle one voice circuit. The carrier frequencies are spaced to provide a bandwidth of about 2,500 cycles for the voice signals, plus an additional amount to allow for imperfections of one kind or another in the equipment, such as bandpass filters which cannot be made to have either perfectly rectangular attenuation characteristics, or perfect stability with respect to temperature. Any form of modulation may be used on the multiplexing carriers, and its choice will either dictate the maximum number of voice circuits which can be derived from the common circuit, or it will be limited by a requirement imposed on the designer to produce from the common circuit a maximum number of derived voice circuits.

Having produced a system deriving several circuits from a common one, each of which has a bandwidth of about 2,500 cycles, it follows that the previously-mentioned telegraphic services, individually requiring much smaller bandwidths, could be applied to such a voice circuit so long as the telegraph circuit signal frequencies were confined to the voice-frequency band, 250 to approximately 2,750 cycles.

Figure 1 illustrates the application of frequency division multiplexing principles to a wire or radio circuit having essentially a flat frequency response from 0 to 30,000 cycles. It is based upon the use of amplitude modulation of the carrier frequencies with the carrier frequencies suppressed and bandpass filters used to only permit transmission of the lower sideband. Carrier frequency assignments are indicated by dotted lines with arrowheads. The associated lower sideband is indicated by a box to its left containing a number which identifies the circuit so derived. Circuit 1 has no associated carrier frequency assignment. It needs none because it is applied directly to the wire or radio circuit without translation.

The second method, time division multiplexing, involves only one basic difference from the frequency division system in deriving the desired circuits. It transmits over the radio or wire facility only one message at a time. A period of time called the repetition or sampling rate, which is short with reference to the highest frequency present in the voice or signal circuits, is divided into a number of parts, usually equal to one more than the number of signal circuits to be applied to the radio circuit. During a relatively small portion of each such part a connection is electronically made to each of the signal circuits in turn, until all have been sampled. Following this a sample is taken of a reference signal, used for maintaining proper synchronism with the distant demodulation equipment. Each sample is proportional to the signal voltage present in its circuit at the instant the sample is taken. Each sample is used to alter some distinctive characteristic, such as amplitude, or position relative to an index position, of a pulse produced by a local pulse generator. Basically these pulses occur at the repetition rate and are delivered to the modulating equipment where the signal samples modify them. These modulated pulses then are used to modulate the radio carrier.

At the receiving terminal the pulses are sorted out and delivered to their proper demodulators. The outputs of these demodulators, of course, are samples of the original signal voltages, which are passed through a low-pass filter to remove all frequency components higher than the useful frequencies intended to be delivered, and by this process the original signal is synthesized. Obviously the audio fidelity of the recovered signal is almost entirely a function of the repetition rate. It is for this reason that most time division multiplexing systems require bandwidths in the radio spectrum which are much wider than we have been used to in the past. In fact, it is this characteristic combined with the number of derived circuits and repetition rates selected that makes it impractical to apply such systems to conventional wire or cable circuits. Generally, they are applied to high-frequency radio circuits. Where pulses are used with a form of modulation in a system permitting severe filtering, (referred to square-wave pulsing) economies in bandwidth can be obtained which would permit use on wire or cable circuits which are corrected to better than 120 kc.[1]

Referring to Figure 2, the time division system basically involves the equivalent of two distributors connecting the derived circuits together, in succession as they rotate in synchronism, through the common circuit.

General Description of the System

The radio equipment to be multiplexed offered an audio band of about 200 to 30,000 cycles. It operates with carrier frequencies between 950 to 960 megacycles. Due to the choice of seven derived circuits as a maximum, and the bandwidth available, frequency division multiplexing appeared to be the logical selection and is the system which will be described. To be reasonably economical in the use of the 30-kc spectrum, the modulation system selected was ampli-

Figure 2. A scheme illustrating the basic theory underlying time-division multiplexing systems. The refinements required to handle speech signals are responsible for the detailed differences between the above and actual systems used. Additional refinements are required where there will be any limitation of bandwidth by the transmission path indicated as the common circuit. Radio usually will provide this circuit

tude, single sideband, with the multiplexing carriers suppressed in balanced bridge circuits. The desired sidebands are selected by the use of bandpass filters having cutoff characteristics giving signal-to-noise ratios better than 50 decibels in all multiplexed circuits. This system has been designed to provide a maximum of six multiplexed circuits, each with a bandwidth of 250 to 2,800 cycles. In addition, of course, the radio can be modulated directly from a seventh circuit, and the bandwidth in this case is 200 to 2,800 cycles. Figure 1 illustrates the band assignments. The radio bandwidth will be responsible for reducing the bandwidth of the direct or voice-frequency circuit, noted previously.

The signals applied to the multiplexing equipment by the connected telephone lines amplitude modulate the multiplexing carrier frequencies in a ring modulator circuit. Copper-oxide rectifiers are the nonlinear elements in this circuit. The circuit has a bridge configuration as far as the signal is concerned in its relationship to the multiplexing carrier. The panels containing these circuits are called frequency translator panels, or translators for short. In Figure 4, which shows one terminal of field test equipment designed to provide for three telephone circuits, and a fourth circuit to be used for telegraphic services, the sending and receiving translator panels are second from the top and fourth from the bottom, respectively, of the rack frame in the cabinet.

Figure 3 is a block diagram of the electrical arrangement of the equipment in this cabinet.

The translators have some insertion losses so that in order to adjust signals to desired output levels it is necessary to employ amplifiers. In Figure 4, the top panel provides a 2-stage amplifier which has a flat amplitude characteristic between 3,000 and 30,000 cycles, and is used to amplify the common output of the sending translator. In Figure 3 this amplifier is indicated by the triangular symbol enclosing the initials *HF*, for high frequency.

For the outputs of the receiving translator, three amplifiers are shown in Figure 3 by the same symbol, but enclosing the initials, *VF*, for voice frequency. In Figure 4 these three amplifiers are on the three bottom panels. For this model, standard audio amplifiers available from stock were used, since they offered satisfactory characteristics and gain.

A third amplifier is indicated in Figure 3, and in Figure 4 it is the panel located immediately below the jackfield panels. This is a compressor amplifier which serves three purposes:

1. It provides amplification for the direct voice-frequency circuit to permit weak signals to properly modulate the radio transmitter.

2. Its gain also compensates for the insertion loss of the low pass section of the separation filter.

3. It is arranged to reduce the dynamic range of speech to permit higher average level of radio transmitter modulation without over modulation.

A standard amplifier was taken from stock and modified for the test equipment.

The multiplexing carriers are obtained from a carrier supply panel, seen in Figure 4 as the panel directly below the compressor amplifier just described. As can be seen from the block diagram, Figure 3, the carrier supply panel provides three carrier frequencies for both the sending and receiving translators and, in addition, de-

Figure 4. Door removed from multiplexing equipment cabinet to show the 4-circuit equipment. Panels are mounted on standard 19-inch rack frame which is hinged to permit access into cabinet and to rear of panels

Figure 5. Multiplexing translator panel block diagram showing arrangement of parts, electrically and mechanically, for three multiplexed circuits

livers a 1-kc signal for testing and signaling purposes.

It is interesting to note that this equipment can be operated with but one type of tube, exclusive of the rectifier in the power supply. Present design does not include the compressor amplifier in an average assembly; only the other two kinds of amplifiers and the carrier supply use tubes, and they are the *6SN7* type, which also is available in ruggedized form. No tubes are used in the translators or the separation filter panels.

Two terminals of this model equipment were built and placed in service with a microwave radio system in August 1949. As shown in Figure 3 each terminal provided four 1-way circuits in each direction with all circuits and panels arranged with connections through a jack-field panel. This provided flexibility as well as convenience and speed in testing and in making any temporary rearrangements of circuitry.

Translators

The two translator panels shown in Figures 3 and 4 are identical. Each panel contains three translator circuits that are electrically independent except for a common output circuit. See block diagram, Figure 5. The devices are insensitive to direction and can be used either for sending (modulating signals on carriers) or for receiving (demodulating or recovering signals from incoming signals); thus the output circuit becomes an input circuit when it is used for receiving. The only difference between the translator circuits is in the pass band of the bandpass filter used between the ring modulator circuit and the common output circuit to select the desired sideband. It then becomes obvious that if each translator circuit is used with a different carrier frequency, its bandpass filter must be coordinated to the carrier frequency. The carrier frequencies used in the field test equipment were 8, 16, and 24 kc, and the pass bands of the associated filters were 5.2 to 7.75 kc; 13.2 to 15.75 kc; and 21.2 to 23.75 kc.

Referring again to Figure 5, the signal path for sending is through a low-pass filter to the ring modulator circuit where the signal combines with the carrier frequency. The output of the modulator circuit contains both sidebands, but the carrier is almost entirely absent. The output is delivered to the bandpass filter which is designed to offer only slight losses for frequencies in the lower sideband range, but sharply attenuates all frequencies outside of that range. The low-pass filter is required for the following reasons:

1. To restrict to the required bandwidth the frequencies of those signals to be transmitted.

2. To pass only the desired lower sideband when used in the receiving direction.

3. To prevent undesirable products of modulation from being delivered back toward the source of signals when used in the sending direction.

4. To prevent variations of impedance in the ring modulator circuit from being closely coupled to the external circuits connected through the filter.

The attenuation characteristic typical of the low-pass filters used in this equipment is shown in Figure 6.

The bandpass filters used in this equipment have attenuation characteristics represented by Figure 7, which shows the curve for a filter having a pass band from 13.2 to 15.75 kc. This filter should be used in a translator to which a 16-kc carrier would be supplied.

The ring modulator circuit used in these translators is shown in Figure 8. The use of contact rectifiers is justified by a number of important reasons:

1. They are obtainable with characteristics more uniform than found in vacuum tubes; in some equipment of this type this permits eliminating all ring modulator balance adjustments.

2. They require no plate and filament power.

3. They have no filaments or heaters to burn out.

4. They are not mechanically fragile.

5. They have no cathodes to lose emissivity.

Figure 6. The attenuation characteristic typical of the low-pass filters used in the translator circuits

Figure 7. Attenuation characteristic typical of the bandpass filters, used to select the lower sideband output of the ring modulators

Figure 8 (above). Schematic for ring modulators used in translator panels. Copper-oxide rectifier elements are used in the ring circuit with series-connected resistors which improve both the overload characteristics, and the balance of the bridge circuit. R_5 and R_6 are provided for vernier adjustment of carrier and noise suppression

Figure 9 (right). Resistance as a function of applied voltage for a copper-oxide rectifier cell

6. They require an insignificant amount of space.
7. They require no socket.

Technical literature contains a number of articles dealing with the use of copper-oxide rectifier elements as modulators and demodulators.[2–6] Each of the referenced articles contributed to the modulator circuit of Figure 8. Figure 9 is a typical curve of the resistance of a copper-oxide disk as a function of the applied voltage. Perhaps the simplest way of explaining how the modulator operates is to treat the copper-oxide ring unit as a double-pole double-throw reversing switch used to connect the output of T_1 to the input of T_3. This connection is poor if each of the four arms of the ring has the same value of resistance, since they form a shunt across the connection between the transformers, and their unpolarized resistance, 20,000 ohms or more, also is in series in the connection. If direct current is applied to the leads marked "carrier," with polarity and voltage sufficient to cause CR_{1A} and CR_{2B} to become conducting it will be observed that CR_{1B} and CR_{2A} are polarized at the same time so that they are less conducting. In this condition of unbalance CR_{1A} and CR_{2B} form low-resistance connections between T_1 terminals 1 and 4, and T_2 terminals 1 and 4, permitting signal current to be transferred through the system with small loss. Then we reverse the polarity of the direct current applied to the carrier terminals. It is seen that now CR_{1B} and CR_{2A} become conducting and CR_{1A} and CR_{2B} have become highly resistant. The connection between T_1 and T_2 still exists, but note that now T_1 terminals 1 and 4 are connected to T_2 terminals 4 and 1, a reversal of the interconnection.

If we substitute an a-c polarizing voltage for the d-c polarizing voltage, T_2 will deliver an output controlled by the frequency and polarity of the applied alternating voltage. If the alternating voltage effective at the copper-oxide elements approximates a square wave, this output would have the appearance shown in Figure 10. It is necessary that the carrier (polarizing) voltage at all times exceed the drop produced by flow of signal currents when they are of opposite polarity. If this excess has insufficient margin the copper-oxide resistance will increase and cause nonlinearity of signal output. This is recognized as amplitude distortion. The slope of the conducting part of the curve in Figure 9 suggests that such distortion will always be present to some degree. If, in addition to insuring that the carrier voltage is always more than adequate to maintain polarization, fixed resistance is added in series with the copper-oxide element, so setting the minimum resistance in the conducting direction to be large compared to the conducting resistance of the copper oxide, then the small resistance variations can be made to be an insignificant percentage of the total resistance. As a result of employing both of these measures we obtained distortion measurements of 0.5 per cent and less for a voice circuit through a sending and receiving translator system with filters but without amplifiers or radio.

The operation of the ring modulator was compared with the action of a double-pole double-throw switch connected to reverse the polarity of the path between

Figure 10. Input signal versus output signal for ring modulator, assuming an applied carrier having a frequency ten times that of the signal, f_s, and of square wave form

Figure 11. Attenuation characteristic for separation filters. These units are combined low-pass and high-pass filters having common output terminals, but separate terminals for the inputs to low-pass and high-pass sections

input and output. This suggests that the carrier signal applied to the ring modulator should be a square wave carrier. In practice it is customary to use a rather large carrier amplitude, supplying it to the ring modulator through an external resistance which acts as a current limiting device.[6,7] As the ring modulator elements polarize, a carrier current begins to flow and attempts to increase. This results in an increase in the drop across the series resistor, thus limiting the current and producing an approximate square wave carrier drop across the ring modulator elements. It is found, however, that signal currents still must be kept small compared to the carrier.

Mr. Cusack has shown[4] that the nonconducting elements in the ring modulator will overload with a signal less than one-tenth that required to overload the conducting elements. He also shows that the use of resistance in series with each element of the ring can radically reduce this difference.

A further and very important result of the addition of the fixed resistors in the ring modulator is the marked improvement obtained in the balance of the circuit. It can be obtained, of course, only if the resistors used are sufficiently well balanced. It is found that resistors having 1 per cent resistance tolerance gave excellent results. The indirect result of the balance improvement obtained in this manner is the possibility of not requiring ring-modulator copper-oxide elements that are as well balanced as was formerly required.

Filters

Filters are used at several points in this equipment, as can be seen in Figures 3 and 5. In Figure 3, two separation filters are shown. Each consists of a low-pass filter, cutoff at 2,800 cycles, and a high-pass filter with its cutoff at 5,200 cycles. These two filters are combined in one case and have common output terminals but separate input terminals. Their attenuation characteristics are shown in Figure 11.

The separation filter is used to apply a separate or direct voice frequency band to the radio transmitter without frequency translation. By applying it through the low-pass filter, the bandwidth of the voice-frequency circuit is restricted to frequencies below about 2,800 cycles, insuring that no higher frequencies accidentally or intentionally present in the voice frequency circuit will interfere with the high-frequency signals delivered by the translators.

An equally important function also is served. By design the impedances of all filters are about 600 ohms in their pass bands only. Outside of these bands the impedances rise to much higher values. Thus the outputs of two properly designed filters with pass bands in different parts of the spectrum can be paralleled and connected to a 600-ohm circuit without causing the circuit to become a 300-ohm circuit. Such isolating effects are quite important to the frequency response of the derived circuits and for avoiding other undesirable noise effects.

In Figure 5, it is observed that two filters are used in each translator circuit. Again, signals from the voice circuit are passed through a low-pass filter, the ring modulator, and then the bandpass filter. The reasons for their use have already been discussed, but no mention was made of the part the bandpass filters play in permitting the several 600-ohm output circuits to be paralleled and then connected to a 600-ohm load. The attenuation characteristic typical of the bandpass filters used is indicated in Figure 7, while Figure 6 shows the attenuation characteristic of the translator low-pass filters.

Carrier Supply System

It is conventional to use free-running local oscillators for supplying the multi-

Figure 12. Block diagram of carrier supply system showing method of obtaining the output signals required. The 8-, 16-, and 24-kc outputs are converted to square wave output before being used for multiplexing carriers

Figure 13 (above). Schematic of fork frequency unit. It consists of a 2-stage resistance coupled amplifier with two feedback paths set up between output and input. One path is through the fork unit and determines the frequency of oscillation; the other employs a varistor in cathode circuit feedback to increase stability and regulate output signal voltage

Figure 14. Carrier supply circuitry

(A) When a signal of frequency, f, is applied to the doubler input terminals, a new frequency, $2f$, is obtained at the output

(B) The frequencies, f_1, and f_2, to be mixed, are chosen so that their difference will equal one of them, while their sum equals the desired new frequency, f_3; the filter, L-C, is resonant at f_3

plexing carrier frequencies. Thus the signal frequencies recovered at the receiving terminal in a single-sideband system will differ from the original signal frequencies by the differences between sending and receiving carrier frequency oscillators. Recovery of speech signals is quite satisfactory even though such differences are as high as 20 or more cycles per second. Maintenance adjustment of these oscillators is required only to keep speech intelligible and as natural as the user requires.

Some forms of telegraphic services, when handled over one of the multiplexed voice circuits, cannot tolerate these rather large differences between original and recovered signal frequencies. This is due partly to the narrowness of the receiver filter, which cannot reasonably be broadened. It is further complicated by the fact that the telegraph sending oscillators may not be perfectly stable or may not have zero temperature coefficients.

Carrier oscillators require careful design to minimize the effects of temperature and voltage variations, and to obtain best stability characteristics compatible with the price at which they will have to sell. They must include provisions for adjusting their output frequency, and also may contain output level regulating means. When high accuracy is required of the recovered signal, the local oscillators at the receiving terminal may be automatically controlled by a carrier or synchronizing signal transmitted between terminals, possibly on the pilot frequency. Another method is to transmit some of the sending end carrier over the system and recover it for demodulation purposes at the receiving terminal.

Local oscillators and their associated adjustments and maintenance requirements are not desirable for the type of multiplexing equipment which would be most suitable for use in electric utility communication systems, especially when we considered that it would be rare indeed when telegraphic services would not be handled—telemetering, load-control, even relaying. A carrier supply system should be so precise and stable that it would require no maintenance of frequency. Moreover, there would be no adjustments in the system which could alter any carrier frequency so much that any circuit would fail because of tampering or misadjustment of frequency controls.

With the multiplexing carriers spaced 4 kc apart, this frequency could be made the source of all carrier frequencies required by the assignments shown in Figure 1. Study of ways and means for obtaining 4 kc with an accuracy and stability of about 0.001 per cent was begun. It was found that a temperature compensated fork frequency standard offered the surest, simplest source of the required signal. By the use of copper-oxide bridge-connected rectifiers and suitable coupling transformers, the fork frequency could be doubled and re-doubled as many times as required to obtain the carrier frequencies. The final decision was for a 1,000-cycle-per-second fork frequency standard, and the block diagram for the carrier supply panel took the form shown in Figure 12. The decision on this frequency was based principally upon the availability of a suitable fork operating at 1,000 cycles and using one *6SN7* tube for drive and output. Furthermore, this frequency would be a convenient signal frequency for test purposes, so the plans for the carrier supply included that provision.

Referring to Figure 12, it is seen that the output of the fork unit is applied to a doubler through a cathode follower with the 1-kc test signal output taken from the cathode of this tube. The signal is doubled and redoubled to deliver 4 kc to a second cathode follower which permits taking 4-kc output without loading the doublers. In addition, the 4 kc is doubled and redoubled again, and the 8-kc and 16-kc signals so derived are amplified and then divided between the 8-kc and 16-kc output circuits and a mixer stage which combines them to deliver 24 kc to a third output circuit. The output circuits are in the form of amplifiers having opposed diode shunt clippers in their grid circuits. This results in delivering three carrier frequencies, 8, 16, and 24 kc, of approximately square wave form.

The fork standard unit was purchased as a complete, tested and calibrated as-

Figure 13. Block diagram of Johnstown multiplexing and line equipment

sembly and was mounted directly upon the carrier supply panel. The fork itself is in a partially evacuated metal container which protects it from atmospheric changes, corrosion, and tampering. It is of bimetallic construction, and the resulting temperature coefficients are better than 0.0001 per cent per centigrade degree between 0 and 100 degrees centigrade. The unit is set to 1,000 cycles per second within 0.0001 per cent at the factory. A vernier frequency adjustment is provided which has a range of about 0.005 per cent, or only 0.05 cycle per second at 1,000 cycles. If another 0.05-cycle error is added for a temperature difference between terminals of 50 degrees centigrade, the total difference in frequency of the forks might be about 0.1 cycle. This amounts to 2.8 cycles for the 28-kc carrier in this system, or an error in the recovered signal frequency of 1.13 per cent for a signal of 250 cycles. The fork is electromagnetically driven, made of a magnetic metal, and polarized by means of a small permanent magnet included in the device. The magnetic flux path links both tines of the fork, a grid or pickup coil and a plate or drive coil. Motion of the tines modulates the flux because the air gaps are being changed, and a small voltage is induced in the two coils. Figure 13 is a schematic of the fork frequency unit.

The schematic of the basic frequency doubler used in this panel is shown in Figure 14(A). C_1 and C_2 are chosen to obtain maximum accentuation of the ripple output of the bridge-connected rectifier, but commercial tolerances are good enough and no adjustments are required to obtain satisfactory operation. The value of R is determined roughly by the safe amount of direct current which can be handled by the rectifier and has little effect upon the ripple amplitude in the range used. It is interesting to note that the $2f$ output voltage of this doubler is about the same as the input voltage across the rectifier. Each doubler used has the same schematic; as frequency increases the transformers, capacitors, and resistors also change correspondingly.

When the desired carrier frequency falls between those obtained by the doubling process, two of the frequencies already obtained are selected and applied to the grids of the mixer circuit of Figure 14(B). Mixing takes place in the plate circuit, and the three frequencies then present are coupled to a high-Q resonant circuit adjusted for the desired frequency. The range of the adjustable capacitor permits peaking, but will not prevent operation on frequency unless it is short circuited. Filtering by this simple circuit is sufficient so that the output of the amplifier contains only insignificant amounts of the two original frequencies. The entire carrier supply system can be placed in operation with no adjustments of any sort required either to obtain correct operating frequencies, or to obtain them so accurately determined that for all known applications no synchronism adjustment need be made.

Amplifiers

Only one of the amplifiers used in this equipment is of interest in this paper. It is the *HF* (high-frequency) amplifier. As seen in Figure 3, this unit amplifies the output of all the sending translator circuits. It must not only have a flat amplitude response from at least 5 kc to 30 kc, but it also must have extremely low intermodulation distortion to prevent causing crosstalk between the several signal circuits as they are amplified in this common unit. The unit is a 2-stage push-pull amplifier, with some feedback, and with transformers in the input and output, resistance-capacity coupled interstage. Two *6SN7* tubes are used in such fashion that should one tube fail or the heater burn out, the other will continue to provide a working amplifier on a single-ended 2-stage basis. Under such conditions the gain will be reduced, and the distortion will increase, but the multiplexed circuits will be maintained.

Field Test Program

Another technical paper[8] deals with the field test program in detail. Figure 3 is the block diagram of the multiplexing equipment used in this program, and Figures 15 and 16 show, respectively, the complete block diagram for the Johnstown terminal, and the two small cabinets, one of which contained the multiplexing equipment and the other required to house the 4-wire sets (hybrids, and so forth), the dialing and code signaling units required by the three telephone circuits to be handled between Johnstown and Seward. These telephone line facilities are not unusual, and their arrangement on Figure 15 is conventional.

It will be seen that the direct or voice-frequency circuit is not provided with a 4-wire set or signaling unit. In the receiving branch, it was equipped with an equalizer amplifier to improve the low-frequency response down to 150 cycles. The field test program included tests of simultaneous operation of all ten audio tones of a line of telegraph equipment, the lowest of which was 150 cycles. From the output of the equalizer amplifier, the receiving branch was connected to the paralleled inputs of the tone telegraph receivers, shown in the block diagram of reference 8. Similarly, the sending branch was connected to the parallel outputs of all ten tone telegraph transmitters. The telegraph circuits thus provided were to be used for several telemetering circuits, two relaying circuits, and for field testing a new supervisory control system.[8]

The data which follows gives the performance first obtained over the radio circuit between Hilltop (Johnstown, Pa.) and the temporary location of the Seward terminal at Armagh. This radio circuit involved a line-of-sight path which grazes Conemaugh Gap at least at one point. Measurements were made on all circuits terminated at each end with 620-ohm carbon resistors. The three multiplexed circuits, as Figure 15 shows, were set up for regular telephone service and were measured with hybrids balanced for the resistive terminations, and amplifier gains adjusted to give zero net-loss circuits in each direction. Frequency response for the Piney circuit, multiplexed with an 8-kc carrier, with respect to the level of the 1,000-cycle-per-second reference, was down 3.7 decibels at 250 cycles, and down 9.0 decibels at 2,800 cycles. The data showed need for equalization, somewhat under 6 decibels per octave, to give a circuit flat within 6 decibels.

Frequency response of the Altoona circuit, (16-kc carrier) was down 6 decibels at 250 cycles, and 5.5 decibels at 2,800 cycles. The Glory circuit (24-kc carrier) was down 7 decibels at 250 and 2,800 cycles. These frequency responses provide excellent talking circuits, and are flat enough to permit being equalized within 1 or 2 decibels where particularly strict requirements exist.

In testing this multiplexing equipment in the laboratory before shipping into the field, the measured noise levels in all circuits were more than 65 decibels below 0 dbm (decibels below one milliwatt). Measurements in the field varied, largely due to conditions in the radio circuit, and were never as good as found in the laboratory. The Piney (8-kc) circuit showed noise levels from 35 to 48 decibels below 0 dbm. The Altoona (16-kc) circuit had noise levels from 41 to 48 decibels below 0 dbm. And the Glory (24-kc) circuit recorded 38 to 60 decibels below 0 dbm. Usual readings for all three circuits gave noise levels more than 40 decibels below 0 dbm.

Figure 16. Doors removed from cabinets housing the multiplexing and line equipment shown in Figure 15

Distortion proved to be hard to measure. Use of the usual noise and distortion meter was unsatisfactory because harmonic distortion has been found to be less than the noise readings. This meter will therefore indicate the noise level as being the per cent harmonic distortion; for instance, 1 per cent if the noise level is 40 decibels below 0 dbm. As soon as the meter is switched to noise measurement the reading is found to repeat itself immediately. It was necessary to measure distortion in terms of intermodulation per cent. This system permits filtering out most of the noise since it operates on signals having levels higher than the noise level. Intermodulation percentages were found to run from 1 to 5 per cent. Experience indicates roughly that 4 per cent intermodulation distortion compares with about 1 per cent harmonic distortion.

Crosstalk tests were made with the aid of a special device. It consisted essentially of six magnetic-tape playback heads with separate amplifiers and output circuits, and a single-drive motor, shaft and tape pulling arrangement. Six tapes were made into endless loops after placing in the machine, and thus any signals recorded in them were played back and repeated as long as the machine was run. The output from one or more speech-recorded tapes was applied to the multiplexing equipment circuits as desired, all at 0 dbm levels to obtain measurements of crosstalk appearing in silent circuits. The noise meter was used to measure any increase in noise level as being the contribution made by crosstalk; at no time was crosstalk responsible for raising the noise level more than 2 decibels. Simultaneous listening tests showed that crosstalk was found to be very slight.

In these comments no mention has been made of the performance of the direct voice-frequency circuit. This is because the use of a special equalizer to boost the 150-cycle-per-second performance also increased the noise output about 15 decibels. This equalizer provided about that much more gain at 60 cycles than it did at 1,000 cycles, and resulted in disproportionately increasing the hum level of the

radio receiver output. The use of pre-emphasis at the radio transmitter will eliminate the need for this equalizer and will permit obtaining noise levels on the voice-frequency circuit, which will be of the same order as indicated for the other three circuits. The original data taken gave a frequency response down 3 decibels at 150 and 2,800 cycles. Noise level at that time was 24 decibels below 0 dbm, and was identified as being 60-cycle hum.

It is interesting to note that throughout the test program there has never been any occasion to question the carrier supply system. It has performed flawlessly in supplying accurate and stable carrier signals. The only tube failures experienced to date evidently were the result of shipment of the equipment from the laboratory to the field.

Conclusions

To date the results of tests made on the multiplexing equipment are evidence that noise and crosstalk requirements of down 50 db or more below 0 dbm reference level can be obtained. Further evidence shows the distortion products delivered by this equipment are extremely small, generally being masked by the noise level so that usual methods of measuring distortion are useless. It is concluded that the radio circuit will introduce most of the noise, distortion and crosstalk, and that great care should be taken to see that the radio line-of-sight path is as nearly ideal as is possible.

Where the full capabilities of the multiplexing equipment are to be required; that is, seven voice circuits, with 50 decibel signal-to-noise and crosstalk ratio, it becomes extremely important to apply the radio circuit conservatively, making certain that 50 feet of clearance is obtained to the line-of-sight for the radio beam.

It is a bit early to put on record any statement regarding tube life. Heaters are operated about 5 per cent below rated voltage, and the *6SN7* tubes have an excellent record even at normal heater voltage. Emission requirements are always less than tube ratings, and in most cases are about 50 per cent of rating. It has not, therefore, been considered economically sound to equip the multiplexing equipment with the ruggedized version of the *6SN7* tube. Since no tube is being operated at a critical point on its characteristics, any good tube will work until emission fails to meet the load.

The carrier supply system has never required any attention. It has been checked for carrier output voltages (loaded) and waveform, and no variations were found. No means was available for checking the accuracy of the frequencies as no ordinary audio oscillator can be used even if especially calibrated because its dial cannot be read with sufficient accuracy. Two carrier-supply panels, one at each end of the radio circuit, were checked against each other when first put in operation, and were found to be drifting in and out of synchronism several times a minute. Again, mostly out of curiosity, the fork frequency standard vernier adjustments were changed enough to effect synchronism and no further adjustment has ever been made. The frequencies of the two forks, located about 12 miles from each other, remain essentially in synchronism over the ranges of temperature experienced to date. Both summer and winter seasons have been experienced and the rooms where the equipment is located normally have no heat, unless work is being done on the test program.

The quality of speech received over this equipment is excellent considering its restriction to a 2,500-cycle-per-second bandwidth. From measurements as well as listening tests, it is better-than-average performance of standard communication equipment in use for this purpose with wire lines.

Discussion

R. H. Miller (Pacific Gas and Electric Company, San Francisco, Calif.): The multiplexing equipment described by the author is of a much higher degree of stability than the equipment commonly available, and is also characterized by extremely simple circuits.

Both of these factors are of considerable importance to power utilities in that a minimum of attention and adjustment should be required.

The high degree of stability of the carrier supply makes it feasible to install the equipment in unheated shelters, without experiencing excessive frequency drifts due to temperature changes.

In general, the use of frequency division multiplexing should be adequate for most power utility applications of microwave equipment, as the large number of channels available from time division multiplexing rarely will be needed on power utility communication systems, and, in fact, might be a disadvantage due to the concentration of too many channels in one microwave system with the possible loss of the complete system by trouble in one piece of the radio equipment.

The technique described for the measurement of cross-talk is most interesting, and the fact that such an elaborate system of measurement was required should indicate a very low degree of cross-talk in the equipment.

It would be interesting to have the author comment on the reason for the selection of a system using an individual fork drive for each channel, rather than having a single base frequency fork and using harmonics of this fork for controlling the various channel oscillators. In such an arrangement the frequency and phase of each channel would be fixed with respect to each other.

F. S. Beale: The author wishes to express great appreciation for the discussion presented by Mr. Miller.

The reasons for the selection of a single fork frequency standard as the common source for all frequencies used for signaling, and as carrier frequencies for use in deriving telephone circuits, included the following:

1. The stability of all frequencies was determined by that of the fork;
2. Frequency and phase, as Mr. Miller points out, are fixed with respect to each other;
3. Carrier frequencies chosen at 4-kc intervals are in rather common use, and a fork frequency source was compatible with such system;
4. Choice of fork frequency permitted using its output directly for signaling and test purposes, eliminating the need for a separate source which would be required by any telephone signaling system;
5. The accuracy of such signaling frequency was such that it became practical to use a simple bridge circuit to obtain amazingly sharp selectivity in the signaling equipment, positively assuring complete freedom from any false signaling due to

presence in speech of the signaling frequency, even if at high amplitude; and

6. Carrier and signaling frequencies were obtainable without tuning adjustments, eliminating the opportunity such adjustments offer for misadjustment.

In closing, it may be of interest to note that since March 15, 1950, at which time the manuscript for this paper was submitted, the two carrier supply panels undergoing the field test mentioned in the paper have performed with no tube failures, no tubes replaced, and no failure or deviation of output frequencies in the five additional months of service.

The Bonneville Power Administration Relaying and Reclosing Program

CLIFFORD C. DIEMOND
MEMBER AIEE

DONALD L. WYLIE
ASSOCIATE AIEE

EXPERIENCE on the Bonneville Power Administration system has disclosed a number of weaknesses in protective relaying and has shown the need for an extensive high-speed reclosing program on the 230-kv lines.

The initial fault protective devices for the 230-kv system included impedance and reactance distance relays, directional-comparison carrier relaying, and the largest circuit breakers obtainable—2,500,000-kva 230-kv 3-cycle nonreclosing oil circuit breakers. Until quite recently modified-impedance and phase-comparison carrier relaying were not available.

System performance was studied on the Bonneville Power Administration a-c network analyzer for anticipated operating conditions and for actual system breakups which were initiated by simultaneous 230-kv multicircuit outages during lightning storms. The studies disclosed that automatic reclosing at high speed would be of great benefit in maintaining stability, especially during multicircuit outages. These analyzer reviews also established the necessity for replacing the distance relays with modified impedance units and for taking steps to improve the performance of the carrier relaying.

As part of a co-ordinated program to eliminate the difficulties with distance relays, carrier relaying, and circuit breakers and to improve the transmission-system performance, these steps are being taken:

1. Increase transmission capacity by the construction of additional lines, by the use of series capacitors, and by the use of higher nominal as well as higher operating voltages.

2. Improve lightning protective design to decrease the frequency of multiphase and simultaneous multicircuit faults, especially on double-circuit towers.

3. Use modified (restricted impedance) distance relays and high-speed phase-comparison carrier relaying on the long, heavily loaded circuits.

4. Install 3-phase high-speed reclosing circuit breakers in 230-kv line positions.

5. Pursue actively a development program for high-speed relaying using the microwave communications system.

6. Continue and expand the use of automatic high-speed recorders, oscillographs, and automatic fault locators.

7. Continue to encourage the manufacturers in the development of high-capacity high-speed tripping and high-speed reclosing circuit breakers by co-operating in staged tests of new developments.

8. Encourage the manufacturers in the development of new relaying methods and of new relays.

New Transmission Facilities

Figure 1 shows the 230-kv transmission system and the proposed 6-year 230-kv construction program of the Bonneville Power Administration. These needs are based on present knowledge and techniques. It is anticipated that the number of circuits will be reduced and routings changed as a result of technological improvements. Among the new 230-kv lines being considered for construction are some 14 lines from various Columbia River hydroelectric plants to the coastal area, those necessary for completion of the Western Montana–Southern Idaho Loop, the Southwest Oregon lines, and a Southeastern Washington 230-kv loop. Although they are not shown in this diagram, there are also many lower-voltage lines proposed for construction during this same 6-year period.

Series capacitors have been discussed in a previous paper.[1] These present relaying problems which have not yet been completely solved. An installation of series capacitors has been authorized for Chehalis substation. Other applications are being studied.

With regard to higher-voltage transmission, studies and investigations of various phases of the problem are in progress. These include the methods for obtaining the necessary transmission voltages, examination of corona and related problems, and consideration of the various economic questions.

Since construction of transmission capacity has not kept pace with the addition of generation, it will be several years before the remaining points in the program will appreciably reduce investment per unit of system capacity. Meanwhile the program will result in improved service—an extremely important point in itself.

Lightning Protection

Design changes to improve lightning protection should decrease the frequency of multiphase faults and multicircuit outages especially on double-circuit towers. Present efforts are to keep all tower footing resistances low and to use overhead ground wires in certain locations where lightning storms are particularly frequent. Overhead ground wires will continue to be used over the lines for a distance of 0.5 to 1.0 mile from most substations on the system. The primary purpose of these is for the protection of the substation equipment.

Distance Relaying

Limitations imposed on distance relays by the system are brought out in Table I where data, including maximum loadings, are shown for typical Bonne-

Paper 50-164, recommended by the AIEE Relay and Transmission and Distribution Committees and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 13, 1950; made available for printing April 28, 1950.

CLIFFORD C. DIEMOND is with the Bonneville Power Administration, Vancouver, Wash.; DONALD L. WYLIE is also with Bonneville at Portland, Ore.

Acknowledgment is due the many engineers of the Bonneville Power Administration who have worked on and contributed to the program described.

Figure 1. Existing Bonneville Power Administration 230-kv lines and 6-year advance program

Number of circuits shown may be reduced and routings changed as a result of technological improvements now under investigation

ville Power Administration 230-kv lines. These maximum loads are expressed in terms of millivolt-amperes and of approximate apparent impedance (load vectors) seen by distance relays at the line terminal closest to the terminus of the load vector. Consideration of the load vectors and possible surges which could occur without losing system stability demonstrates the urgency of restricting the relay impedance characteristics because the surge vectors are always smaller than the steady state load vectors. Both can be seen to be of a magnitude not much greater than the line impedance. Since surge and load vectors usually appear at nearly unity power factor, the modern modified distance relay[2,3] lends itself ideally as a solution to the problem of restricting tripping to actual faults on the line section. These are capable of being set so that tripping cannot occur for a transient system surge unless the system becomes unstable and the apparent impedance vector[4] passes through the relay impedance characteristic, that is, the system electric center is within the relay reach.

Table I also gives the magnitudes of representative 3-phase faults in megavolt-amperes at 230 kv for a solid fault at the end of the line with the circuit breaker closed and also open at that end. The 3-phase fault impedance seen by distance relays at the line terminal is of course equal to the line impedance Z_1 during these faults.

It is the Bonneville Power Administration plan to use distance relaying for phase faults which is as simple as possible commensurate with the load, fault, and system-surge considerations. It is recognized that if the tripping response of the phase relays is limited to fault and out-of-step conditions, (apparent impedances in the range 45–115-degree lag) a certain degree of complexity must be accepted.

The decision was made to de-activate the out-of-step trip-blocking equipment originally supplied with the distance-relay directional-comparison equipment. It was felt that more satisfactory system operation would be obtained if tripping was permitted by any relay which saw the out-of-step impedance vector within its tripping area. It was considered doubtful that the location of the out-of-step impedance vector could be predicted accurately enough for all load and fault conditions so that tripping could be relied on at selected line locations.

There is little likelihood that out-of-step tripping will open enough lines to completely drop any substation. On the other hand, trip blocking for out-of-step could easily magnify the severity of the disturbance.

The first zones of the modified distance relays are set at 85 per cent of the protected circuit length. Because of the limitations brought out in Table I and covered in the foregoing, the second zones

are set at about 130 per cent of the protected line length with a time delay of 15 or 20 cycles. In order to give the greatest backup for faults on other lines, the third zones are often adjusted to give maximum reach in the reversed direction. By tipping the modified impedance characteristic for all zones away from the system surge vector, the tendency to trip for a swing from which the system can recover is lessened.

The use of modified distance relays gives promise of complete elimination of improper tripouts due to accidental loss of potential. One method of accomplishing this end involves the use of overcurrent fault detectors set above load current in the first-zone trip circuit and offsetting the second- and third-zone elements so that the origin as plotted on an impedance diagram[4] is outside the relay tripping area. This possibility makes the use of bus potential transformers more attractive at all voltages.

Backup ground relaying is provided for most lines by directionally controlled induction overcurrent ground relays equipped with instantaneous trip attachments.

While some of the ground relays now in service are of the product type, it is planned to use no more of these except on short transmission lines, a use which they seem to fit to better advantage than the long-line application. The combination of instantaneous trip attachments in ground relays and phase-comparison carrier relays should give a reasonably fast relaying speed for most faults.

Carrier Relaying

Experience with directional-comparison carrier relaying using the older impedance and reactance relays disclosed several weaknesses in the carrier relaying systems as used on the Bonneville Power Administration lines. The limited reach permissible with the impedance and reactance relays resulted in slow operation of carrier relaying for end-zone faults. There is also considerable doubt that any directional element, whether it is a separate unit or inherent in the distance measuring element, can successfully determine direction when closing in on an electrically close 3-phase fault where the relaying potentials are obtained from the line side of the circuit breaker.

Performance of the directional-comparison carrier ground relaying was also impaired because of mutual coupling between lines for zero sequence currents. For some system operating connections, notably the interleaved Coulee bus,[5] product-type carrier ground relays were subject to improper operations.

The final objections to directional-comparison carrier relaying, as used on the long 230-kv lines of the Administration, lay in its extreme complexity and the dependence of the carrier relaying on proper operation of the distance relays.

Therefore, as a primary system of relay protection, at least until a satisfactory microwave relaying system can be developed, it is planned to replace directional-comparison carrier with modified distance relaying as covered in the foregoing and phase-comparison carrier relaying,[6,7] on the 230-kv network. At the time an adequate microwave relaying scheme is in service, experience and carrier frequency spectrum congestion will dictate further changes to be made.

Phase-comparison carrier is being used in spite of its inability to relay for some 3-phase end-zones faults on long lines. Several considerations are being kept in mind in accepting this restriction. First, the number of 3-phase faults on the 230-kv system is very small. Second, most of these will be cleared quickly by the first zones of the distance relays. The majority of the 3-phase faults which occur in the end zones can be relayed by phase-comparison equipment at the remote end due to the usual increase in fault current (as shown in Table I) after the end nearest the fault has cleared. Finally, if the 3-phase fault current is not large enough to operate the phase-comparison relays, it cannot be classed as a severe fault, so that second-zone relay times of 15 or 20 cycles for perhaps one 3-phase end-zone fault in a total of 500 can be tolerated. The directional-comparison carrier relaying does not do nearly as well for all faults including 3-phase and unbalanced faults.

The phase-comparison relays being current-operated and, independent of voltage, should provide reliable and fast operation for 3-phase faults where failure to trip may occur during a closing in operation with distance or directional-comparison carrier relays. They should not be as subject to the limitations due to mutual impedance as are directional overcurrent ground relays. Of importance is the fact that the phase-comparison equipment is essentially independent of the distance relays, and is mechanically simpler than is the directional-comparison equipment.

Relaying speed with presently available phase-comparison relays should be from two to three cycles for all unbalanced faults including phase to ground, 2-phase to ground, and phase to phase faults. This speed of operation is contrasted with Bonneville Power Administration experience with directional comparison carrier where relaying times of up to 15 cycles have been measured.

At the time of installation of directional-comparison carrier pilot equipment, the equipment was satisfactory for line loadings then considered to be large. It has been since established that line loadings could be raised to much higher levels. With these higher loadings, the older directional-comparison equipment has become inadequate for fault protection where fault and load currents are comparable. Ground fault currents and voltages have also become limiting factors.

Microwave Relaying

Relaying over microwave communications channels[8] shows considerable prom-

†Representative 3-phase end-line faults shown are those from the line terminal given for both terminals closed, normal system, and with the terminal nearest the fault open, line open. Values are given in megavolt-amperes at 230 kv.

Figure 2. Microwave transfer trip circuits

ise of attaining the goal of clearing all faults in less than four cycles with present-day circuit breakers.

The fundamental advantage of microwave communication facilities for relaying is that since the protected line is not used for signal propagation, the chance of coincident failure of the high-voltage line insulation and of the communication channel can be reduced to a negligible factor. The facilities can be used for at least two general relaying methods—a transfer trip and a differential scheme. There are many variations of these, the two herein discussed are presented simply as possible methods.

For the microwave transfer trip scheme proposed, it is planned to use modified directional distance relays as the basic fault locators for phase faults. The scheme takes advantage of the fact that the zone-*1* distance relay elements at the far terminal will operate for end-zone phase faults, as seen from the near terminal.

For example, in a phase-to-phase fault near line terminal *B*, *TT-6* (transfer trip relay number *6*) in Figure 2 will be energized simultaneously with the trip coil of the circuit breaker at *B* by the first-zone distance relay contact. The *TT-6* contact at line terminal *A* would be closed in a time of one to three cycles permitting the second zone at terminal *A* to trip for this end-zone fault with negligible time delay. The *TT-6* relay at *B* operates the *TT-6* contact at *A* over the microwave facilities and auxiliary interposing relays at *A* and *B*.

There are available distance ground relays[9] which could be used for ground relay transfer trip in the same way as for phase faults. However the relaying system shown in Figure 2 presents a method which requires comparatively simple overcurrent elements.

For ground faults, this scheme provides for the use of two instantaneous overcurrent relays at each terminal. One of these is set to operate for low values of fault current (60 to 200 amperes primary), and the other, a so-called "high-set" overcurrent relay, will close its contacts in the range, 1,000 to 3,000 amperes. In addition, a separate directional element to operate in conjunction with the low-set overcurrent relay is required at each terminal. These relays energize transfer trip functions in a manner similar to that covered in the foregoing under phase relaying so that for most system conditions all ground faults can be relayed at both terminals in one cycle from fault initiation.

To cover those cases when a line is energized from only one end as when testing a faulty circuit, phase undervoltage and residual overvoltage relays interlocked with oil circuit breaker (*OCB*) auxiliary switches are proposed.

In order to attain an over-all clearing time of four cycles using 3-cycle circuit breakers, the fault-sensing relays and the microwave channel are required to completely transmit the transfer tripping or differential relaying intelligence in one cycle or less. This may be easily realized in practice. Bonneville Power Administration microwave equipment will provide full duplex voice channels having a transmission band flat within one decibel from 300 to 3,000 cycles. By the use of tone telegraph submultiplexing equipment, it is possible to subdivide the voice channel into one or more high-speed telegraph channels as shown in Table II. The figures in the table represent the theoretical maximum speed of each telegraph channel when the voice channel is submultiplexed by one or more telegraph channels. The finite delay due to electrical propagation in the microwave link and the delay inherent in relay end devices are neglected. Actually the total time requirements including the relay end devices will be about 0.75 cycle greater than the times shown in Table II.

The microwave transfer trip system, unlike present-day carrier relaying, will only be required to transmit relaying impulses when tripping is necessary. This poses a small problem in that it will probably be necessary to monitor the voice channel. This monitoring may easily be obtained by impressing a pilot tone at the bottom end of the voice band. This tone may be isolated from the relaying channels by[4] suitable electric filters. The microwave radio circuits are equipped with a failure alarm to signal the loss of radio-frequency carrier. Another possibility for monitoring of channel continuity is to use frequency-shift telegraphy in which case all relaying channels will at all times transmit a steady tone, the frequency of the tone being shifted when the channel is required to transmit a relaying signal. In this case, loss of any channel tone at the receiver would signal a channel or equipment failure and steps can then be immediately taken to restore service.

Initial equipment being acquired by the Bonneville Power Administration will not employ frequency-shift operation but will be of the amplitude-modulated on-off keyed carrier type, a type which is simpler in design, requires fewer com-

Figure 3. Microwave differential relaying circuits showing pilot-wire system applied to microwave

Arrows denote flow of relaying information

ponents, and hence may be somewhat more reliable in operation. In addition, extensive studies [10] of the relative merits of frequency-shift versus amplitude-modulated telegraph operation indicate that on circuits where the carrier-to-noise level is high and the system is relatively free from signal fading the two systems are essentially equivalent. It is recognized however that, under conditions of low carrier-to-noise ratio and heavy fading, the frequency-shift operation shows a marked improvement over amplitude modulation. This factor will probably be of little importance when operating over microwave radio links. The microwave system exhibits excellent level stability and a high signal-to-noise level at the demodulator output for all carrier-to-noise ratios above the improvement threshold of the system. It is, therefore, likely that except for an occasional outage due to tube failure the microwave relaying channels will be equivalent to or better than power-line carrier in reliability and many times superior to wire lines.

A relatively simple modification of the pilot-wire relay, of which several types are in use in the protection of short Bonneville Power Administration transmission lines, seems to offer a promising field for possible microwave differential relaying. With the microwave system, a 2-way full duplex channel of essentially lossless character may be established for any desired distance, and the limiting factor of present pilot-wire relay systems, namely, line loss, may be eliminated. The limiting distance to which existing pilot-wire relaying systems may be extended is controlled by phase shift of line currents and by the finite propagation delay of the radio channel. The propagation delay may be held to a minimum by delay-compensating networks at each end of the relaying channel, but the total residual delay is always equivalent to at least the line-current phase shift between the two relaying locations. For this reason, it now appears probable that present pilot-wire systems, when adapted to microwave, will find an upper limit of application at line lengths approaching 150 miles. For line lengths in excess of this distance the phase differences between comparison voltages derived from phase-sequence networks at near and distant terminals becomes such that the sensitivity of the relaying system as well as its ability to differentiate between fault and nonfault conditions are greatly reduced.

Figure 3 shows one simple arrangement by which a pilot-wire relaying system designed primarily for operation over wire lines might be successfully adapted to operation in connection with microwave. In order to establish a 2-wire connection at each end of the link it is necessary to employ the hybrids shown. Since the microwave link can transmit intelligence but no significant amount of relay operating power, it is necessary to reduce the normal relay voltages derived from the phase-sequence networks to a low level for transmission to the distant terminal and then employ an amplifier having a fixed gain to raise the received signal to proper level for relay operation. This introduces some complication but with relays of at least one type this can be largely offset, as studies indicate that the relay operating network may itself be used as the hybrid, thus eliminating the two hybrid transformers indicated in the drawing. By simple modifications in circuitry, the microwave channels, which are required to transmit differential relaying intelligence, may be obtained with the lower transmission band extending down to 50 cycles. In this case, by using a low-pass filter to pass frequencies between 50 and 600 cycles the channel may be used to derive simultaneously one pilot-wire channel and four transfer trip channels. Using a pilot-wire channel bandwidth from 50 to 300 cycles, the over-all channel transmission time for the pilot wire would approach 1/4 cycle, and, with sufficiently fast end devices, both ends of the channel could be reasonably expected to initiate breaker tripping in one cycle, which, with 3-cycle high-speed circuit breakers, would give a total line-clearing time of approximately four cycles.

Until experience has been obtained with the microwave facilities and the various relaying schemes tried on an experimental basis, it does not seem advisable to rely on any kind of microwave blocking system. In a blocking system, whether it be of the directional comparison, phase comparison, or of another differential type, a signal must be received from the remote end of an unfaulted circuit to prevent or block operation of the tripping elements for faults external to the line section. Use of two independent microwave channels would probably increase the reliability of a differential blocking system. While this would decrease the complexity of the relaying, it would do so at the expense of the microwave. On the other hand, by use of a transfer trip signal via the microwave channels, the only consequences of microwave failure are to delay clearing of the fault until the backup relays have functioned on the faulted line and possible reclosing failure.

Merely to adapt an existing relaying system to operate in connection with the microwave is not the primary aim of the relaying investigations now being carried on. It is ultimately expected that a completely electronic system will be developed which may in time employ thyratrons as a direct means of circuit breaker tripping with the resultant elimination of most mechanical end devices. There are several arguments for a system of this sort, chief among which may be cited the possibility of imposing almost zero burden on current and potential transformers and the further increase in relaying speed by the elimination of mechanical inertia inherent in present relays. Another argument for development of electronic relays is the ever present desire to achieve a more simple and universal relay operation.

Figure 4. Typical line-to-ground fault distribution curve showing intermediate fault current at 230 kv versus distance for 230-kv Coulee-Midway lines

The vacuum tube with its flexibility and adaptiveness to design offers some important possibilities for investigation[11,12] and members of the Bonneville staff and others are actively exploring this new field. Several interesting electronic relaying systems have already been proposed and present plans call for an active development work in this field concurrent with the expansion of the Bonneville Power Administration microwave system.

Reclosing Program and Circuit Breaker Modernization

Analysis of the several system breakups experienced shows the need for an extensive high-speed reclosing program. In addition, growth of the system requires 230-kv reclosing circuit breakers of at least 10,000,000- and 7,500,000-kva capacity at several substations, many of which are now equipped with 2,500,000-kva nonreclosing breakers. It will be necessary to replace or rebuild a number of breakers for heavier fault-interrupting duty and for reclosing service. Existing equipment which is moved will be used in transformer positions or in other locations where interrupting and reclosing requirements are not severe.

Reclosing on transmission circuits is limited by at least four factors (for lightning-caused faults).

1. The circuit breaker must be capable of high-speed reclosure (12 to 20 cycles).
2. High-speed relaying must be provided which will initiate tripping simultaneously at all terminals of the protected transmission line for highest-speed reclosing.
3. Sufficient dead time must be allowed to permit deionization of the power arc path.
4. Adequate time must be allowed for long duration or repetitive lightning strokes.

Simultaneous high-speed tripping within one cycle of fault initiation must be provided by the relays at all terminals of the faulted transmission line for the fastest reclosing. Phase-comparison carrier relaying at present is not capable of attaining this ideal, but this goal appears possible using relaying over the microwave communication facilities.

Fault-arc deionization appears to be a function of fault duration, fault magnitude, the weather, fault configuration, and magnetic blowout of the arc. Tests indicate that duration and magnitude are the principal factors.[13] High-speed relaying and clearing at three cycles or less at all terminals of the faulted line are essential to successful high-speed reclosure, since these control the duration of the fault.

Data as to the time duration of lightning strokes to transmission circuits are not complete. Investigations involving high structures indicate that a small percentage of lightning strokes have a duration approaching one second in length. Indications are that the great majority of lightning strokes to transmission circuits have a time duration of less than 0.2 second.[14] Deionization time requirements for lightning arcs are believed to be of no appreciable consequence, so that reclosing in 12 cycles (0.2 second) or more will allow for most single repetitive lightning strokes.

Taking all of the above factors into account, it should soon be possible to successfully reach a reclosing time of 15 cycles assuming nearly simultaneous relaying at both line terminals.

To illustrate the importance of high-speed circuit breakers and relays, high-speed reclosing will be compared for limiting conditions—that is, reclosing, for an end of the line fault with high-speed relaying at both terminals and time-delay relaying in 15 cycles.

1. High-speed relaying—3-cycle circuit breakers
   a. Circuit breaker and relay nearest fault—3 cycles
   b. Circuit breaker and relay, far terminal—4 cycles
   c. Reclose terminal nearest fault—15 cycles
   d. Reclose, far terminal—16 cycles
      Dead time for power arc deionization—11 cycles
      Time allowance for lightning—15 cycles
      Line returned to service—16 cycles
2. Time delay relaying
   a. Circuit breaker and relay nearest fault—3 cycles
   b. Circuit breaker and relay, far terminal—18 cycles
   c. Reclose terminal nearest fault—29 cycles
   d. Reclose, far terminal—44 cycles
      Dead time for power arc deionization—11 cycles
      Time allowance for lightning—29 cycles
      Line returned to service—44 cycles

In the foregoing illustrations, the dead-time allowance for arc deionization, 11 cycles, may be longer than necessary where high-speed relaying and clearing is achieved at both terminals. Similarly the dead-time allowance for time-delay relaying may prove to be too short because of the greater deionizing action required for the longer-duration fault. The significant point is that the line cannot be returned to service in less than 44 cycles with 15-cycle relaying.

Fault Location and Automatic Recording

Closely related to system relaying, circuit interruption and reclosing are the problems of fault location and automatic recording. In order to achieve the maximum economy in system operation, transmission circuits must be loaded as heavily as stability considerations will permit. Consequently, it is essential that each point of system fault be investigated immediately after the occurrence of the trouble in order to correct and repair any damage, and, in the case of permanently faulted circuits, to quickly restore the line to service. Since a major portion of the Bonneville system network traverses mountainous terrain where patrol and inspection is difficult even during good weather and especially so during the winter time, and the vast majority of faults are transient in character, it can be seen that methods for quickly locating faults and checking system performance can save much time and money.

Among the devices in use on the Bonneville system for fault location are, of course, patrol by truck, helicopter, and foot; annunciating ammeters; capacitor

fault current devices; magnetic-link fault-current devices;[15] and pulse-type fault locators.[16,17,18,19] Automatic oscillographs[20] are also relied on for fault location and extensively for information about system troubles.

The annunciating ammeters are residual or ground-current-operated devices containing six targets similar in appearance to those found in the trip circuits of most protective relays. These targets and their related coils are calibrated to indicate values of 5, 7.5, 10, 15, 20, and 25 amperes rms.

Data from annunciating ammeters, although easily obtained, are subject to some inaccuracies. They respond to offset currents as well as to those which are symmetrical. Fault resistance is unknown. The current distribution is affected by the sequence of circuit breaker operations. For these reasons, it is necessary to consider other factors than the ammeter indication in estimating the location of a fault on a line.

Nevertheless, experience has been quite satisfactory with this device, considering its inexpensiveness and its simplicity. It is possible to predict successfully the location of faults to within 25 per cent of the line on the average. In some cases, this prediction has been narrowed appreciably from this figure.

Figure 4 shows the line-to-ground fault-current curves for a typical 230-kv transmission circuit. A tabulation of annunciating ammeter reading combinations derived from these curves is also given. As can be seen, a reading of 20 amperes at Coulee and 5 amperes at Midway on the faulted line indicates a fault location between 17 and 25 miles. This estimate, tempered by any other available data on the fault, is given the line patrolmen as the most likely location of the fault. Often because of the difficult-to-evaluate factors mentioned above, it is necessary to patrol several miles beyond the indicated section to actually locate the fault.

Another ground-fault current-measuring instrument in use on the system is one which charges a capacitor through a rectifier in proportion to the magnitude of the fault current. The charge is measured by observing the maximum deflection as the capacitor is discharged through a long time-constant *RC* circuit which includes a microammeter. Current curves similar to Figure 4 are referred to for estimating fault location.

The latest types of fault-location equipment in service include so-called pulse-type devices of various kinds. There have been two types of these in service on Bonneville lines (type *A*[18] and type *C*[17]), and a third is being installed in the summer of 1950 (type *B*[16,18,19]). In one summer's operation of the type-*C* device, of a total of five faults within its operating range of 83 miles, three were predicted within 1.5 miles of the actual location, one was never found, although a good record was obtained, and one was lost because of a processing error during the film record development. Figure 5 is typical of the records obtained with this fault locator. While experience has so far been excellent with these pulse-type locators, they should be considered as still in the development and trial stage. A possible application of the type-*A* instrument to automatic recording of lightning duration and wave shape is also being considered.

All of these pulse-type fault locators provide data only on fault location and not on system stability or performance. As such, failure of the device could result in a complete loss of all data were it the only fault-locating or automatic recorder in service.

Accordingly, it is felt that automatic oscillographs for the recording of currents and voltages in high-voltage transients, especially during system faults, are highly desirable to successful operation. Faults can be successfully located by means of data from these with an average accuracy of approximately five to ten per cent of a given transmission line. Information from these instruments will be invaluable for checking the performance of the other fault locators covered above. In addition, they will be indispensable for analyzing system performance and sequence of electrical events. Such occurrences as relay operations, circuit breaker tripping and reclosing, data on system stability, and machine performance can only be obtained from complete automatic records.

The automatic oscillograph does have limitations. It depends on fault-detecting relays for initiation, and its record length is limited. As a result, it does not completely monitor the power system for all types of disturbances and especially for cases of instability. In the latter, records are usually difficult to relate to each other because of their random nature. This results in inaccuracies in the analyzer studies of system breakups.

Figure 5. Typical pulse-type fault-locator record, type C

Instrument installed at Spokane substation. Line-to-ground fault on 230-kv Coulee–Spokane number 4 line at 8:43 p.m. on August 3, 1949. Fault estimated to be 33 miles from Spokane and actually found to be 34.5 miles from the station

It would be useful in determining machine characteristics and in deciding on transmission system additions or changes to know what happens to all the system elements for several seconds of a disturbance.

In some cases, the performance data for several minutes after the system trouble would be valuable. It would also be helpful to know the exact sequence of events. Many times after the breakup, out-of-phase switching will occur that causes relay operations which are sources of confusion in analyzing the disturbance. Since this switching is done manually, an automatic oscillograph usually provides little data.

For the above general reasons, Bonneville has been actively investigating the possibilities of a magnetic-tape recording instrument for continuous monitoring of the system. There has been issued an invitation to bid,[21] on a multichannel magnetic-tape recorder. The record which would be obtained from this device would be played into a manually controlled magnetic oscillograph which is operated at a slow speed for long-time records and at a high oscillograph speed for detailed analysis of a given transient.

While this system will be more expensive than automatic oscillographs and it will require more effort to obtain records, there is so much to be gained in improved knowledge of transmission-system performance that it is felt that the investment necessary for several tape recorders is more than justified. The data which can be obtained will be very useful in making complete studies of system disturbances, studies which may involve the future investment of millions of dollars in transmission capacity.

Thought has been given to a short-time 8- to 12-second continuous-loop magnetic-tape recorder. The information which it would provide in addition to that obtained from automatic oscillographs would cover the few cycles immediately preceding the occurrence of the transient which operates the fault-indicating relays. However, it is felt that this small bit of additional data would not warrant the additional complexity of the magnetic-tape system over magnetic oscillographs for short-time recorders.

Future Developments

The Administration will continue its policy of encouragement to relay manufacturers. It is interested in new developments which promise to simplify and to lessen time requirements for relaying, especially on long transmission lines.

When one considers the decrease in costs for 3-cycle 230-kv 7,500,000-kva and 10,000,000-kva reclosing circuit breakers alone, from about $100,000 to $50,000, the development and testing program of the circuit breaker manufacturers, the United States Bureau of Reclamation, and the Bonneville Power Administration can be seen to be more than justified. These lessening costs have been to a large extent attributable to developments which followed and were proved by tests on the Administration system.[23,24,34] This saving will apply to many future installations not only on the Bonneville system but on other transmission networks.

Among the new developments, which the authors believe should be taken under consideration by the manufacturers, is a circuit breaker still faster than the 3-cycle circuit breakers. It does not seem that too many advances need to be made in order to obtain a 2-cycle high-capacity circuit breaker. When the improvements made in interrupting capacity in just the last few years from two and a half million kva to over 10 million kva are considered, this speed-up in interrupting time does not seem at all out of line.

While adequate interrupting capacity is essential, the lower fault-interrupting duties must, of course, be kept in mind. The great preponderance of the fault interruptions required of a 10,000,000 kva circuit breaker on the Bonneville system is in the range from 2 to 25 per cent of interrupting rating. It is as essential that these be interrupted at high speed as for the heavier faults.

The question immediately arises as to the real need for a 2-cycle circuit breaker when 3-cycle equipment is now available. It is believed that the development can be easily justified and is in fact warranted to go along with anticipated relaying improvements. First of all, system stability will be improved. The initial shock due to the fault will be decreased. Bonneville Power Administration studies indicate that fault-arc deionization will be more rapid because of shorter fault duration. Hence it is likely that faster reclosing will be possible. The over-all result is an improvement in stability, an increase in system-load capabilities, and improved service. While the gains appear small percentagewise, they are in actuality large when measured against transmission-system investment.

While it is perhaps oversimplifying a complex subject to apply percentage multipliers to the total system, it can be unhesitatingly stated that faster relaying, fault clearing, and reclosing can be evaluated at several million dollars.

Discussion

W. A. Morgan and **R. W. World** (Bureau of Reclamation, Denver, Colo.): The authors are to be commended on a thorough presentation of a complex subject. Those of us who have heard partial information from time to time on the Bonneville relaying program have had most of our questions answered by this paper.

The Bureau of Reclamation is interested in any new ideas or devices that will improve system performance, because any improvements actually result in large savings in system design costs in the future. The application of microwave channels for speeding up relaying appears to be feasible, and we know of other systems where it may be used if it proves to be practical and economical. Also, the encouragement given to the further development of electronic relays is given a second from the Bureau as this will mean a step toward the goal of maximum speed and simplicity in relaying. When one looks at a complicated mechanism such as a relay or a governor for a hydroturbine, it is not difficult to imagine that these devices with their inertia and friction will some day be replaced by electronic tubes.

With regard to the use of transfer tripping, instead of blocking, on microwave, it appears that there is some advantage for reliable transfer tripping on a 2-terminal line. In fact, it would be desirable to have a transfer tripping scheme sufficiently reliable so that fault detectors would not be required at the receiving terminals. The authors did not bring out the greater advantage of transfer tripping to be found on lines having more than two terminals. The use of these multiterminal lines is an economic necessity in some cases, and it appears that simultaneous tripping would be possible with transfer tripping, whereas sequential tripping is usually all that is possible with blocking-type carrier relaying, because of the mutual impedance effect and

other causes. However, the Bureau has had difficulty with a carrier transfer trip scheme and it is hoped that similar difficulties are not experienced with transfer tripping by microwave.

It is understood that it is planned to have high-speed circuit breaker reclosing on the interim relaying scheme which will use phase-comparison carrier relaying, even though simultaneous clearing for all 3-phase faults will admittedly not be possible. The authors realize they are taking a calculated risk. It is desired to point out that this risk may not be tolerable on other systems where the percentage of 3-phase faults is greater than on the BPA which does not have continuous overhead ground wires. The BPA probably can show data to indicate that perhaps only 2 per cent of their total faults are three-phase. However, other systems having overhead ground wires on steel towers in New York as well as the Tennessee Valley Authority,[1] have records to show that as many as 30 per cent of the total faults are of the 3-phase type and this may be explained by analysis. It is to be recognized, of course, that the total number of faults on a system with overhead ground wires would be only a fraction of that for a system without overhead ground wires for the same lightning frequency. BPA is fortunate in being in a low lightning frequency area, but it is believed that frequent system break-ups might result if this policy were used in a higher frequency lightning area. Thus, it is desired to point out that most systems which have overhead ground wires might find it risky to minimize the importance of 3-phase faults and use phase-comparison carrier rather than the conventional carrier current relaying.

The Bureau of Reclamation's experience with special long-line type distance carrier has been good. It is believed that one of the causes for BPA to turn away from carrier was their experience with improper ground-relay operation because of the interleaved Coulee bus. However, now that the Bureau is installing 10,000,000-kva interrupting duty circuit breakers, all busses will be solidly, electrically connected together at Coulee power plants and the difficulties from use of the interleaved bus should not again occur. So, it is felt that we should not unjustly condemn carrier relaying but should look at the facts on both sides of the case. If this is done it is believed that carrier relaying can do a good job, if given a chance.

The scheme the authors propose for preventing false tripping of distance relays upon accidental loss of potential has possibilities. Where fault currents permit, as on long lines, why not use the overcurrent relays as independent tripping elements and offset all three zone elements to exclude the origin? Then, memory action would no longer be needed; tripping would be fast and positive when closing on a near fault; there would be fewer contacts in series in the tripping circuit; separate directional elements could be eliminated; the characteristic circles of all three zones would be smaller to give better assurance against undesired tripping during power swings without sacrificing speed in clearing faults; incorrect directional element operation resulting from capacitor potential device transients would be prevented; and relay targets would provide greater indication of fault location. The only adverse effect of capacitor potential device transients would be to slow up the distance element pick-up for faults near the balance point, an unimportant consideration on long lines where far-end faults do not greatly depress the station voltage.

In conclusion, I would like to say that the Bureau has recognized the weakness of using line potential as compared to bus potential in that a distance relay cannot distinguish direction when reclosing on a close-in fault using line potential. It has been our policy to use bus potential wherever possible without having to switch bus potential.

1. Performance of 161-Kv and 115-Kv Transmission Lines, K. E. Hapgood, C. P. Almon, Jr. *AIEE Transactions*, volume 66, 1947, pages 863–69.

J. L. Blackburn and **S. L. Goldsborough** (Westinghouse Electric Corporation, Newark, N. J.): This paper is a valuable contribution in outlining the relay practices and thinking of a large power system for the protection of their major transmission network. There are a number of statements on which more information would be helpful. Other parts require further amplification particularly since they might well lead to false conclusions unless one appreciates the background and reasoning behind them.

Under the section in the paper on Distance Relaying it is stated that out-of-step blocking is being deactivated. This has some merit since, as pointed out, it may be difficult to separate the system at designated points during all operating conditions. On the other hand since the system may be separated at any number of points or several points, it would seem that the dispatcher and operators of the several stations must be well trained to reconnect the system with a minimum of delay.

It is indicated that product-type ground relays are not suitable on long transmission lines for back-up protection. More information on this would be helpful as general experience does not substantiate the authors conclusion. There are two aspects of back-up protection: secondary protection over the primary relays (in this case carrier or pilot wire) for the protected section and: back-up protection for the adjacent line sections.

For the first case, over-all faster relaying times are usually possible with the product-type relays. It should be remembered that all of the several forms of induction-type relays operate on the square of the electrical quantity, or on the product of quantities and as such have the same general characteristics. The degree of inverseness can be controlled within limits as has been done in the conventional induction relays. In the product-type relay only the very inverse type has been made because this characteristic seems best suited to the multiple grounded systems in common use.

In many cases the second type of back-up protection is difficult if not impossible to obtain on multiple grounded systems with any type of induction relay design or curve. This is particularly true where the relays are set to back-up the main section as well as the adjacent section. Instantaneous overcurrent relays can often be applied to protect a major portion of the main line section so that the induction overcurrent relays can be set on the basis of operating for the end zone faults and backing up the adjacent section. For the close-in faults covered by the instantaneous element the induction relay will be operating "off the curve." This is a good compromise as long as the heavy faults do not exceed the short-time thermal limit of the induction relay.

It would be interesting to know whether or not consideration was given to the use of distance relays for ground fault protection.

Under the section on Carrier Relaying it is stated that slow operation of the carrier relaying resulted from the limited reach of straight impedance and reactance relays. It would be well to clarify the meaning of this paragraph. Also it is not clear as to what is meant by the statement that the carrier relaying is dependent upon the proper operation of the distance relays, particularly when they are retained to supplement the phase comparison carrier relays.

The occasional failure of the directional element in the directional comparison carrier scheme to respond to a close in 3-phase fault is treated as a disadvantage of this type of equipment. However, in considering the phase-comparison scheme it is noted that complete 3-phase fault protection may not be possible but in this case several reasons are given as to why this 3-phase failure is not important. It would seem that if this later argument is applied to the directional comparison scheme, then more complete protection would result using the directional comparison scheme.

In this connection there seems to be a feeling that the directional distance carrier scheme is extremely complicated while the phase-comparison carrier scheme is not. This is a matter of relativity. The first scheme has more mechanical elements and contacts while the second has more electronic circuits. Over-all (eliminating the additional back-up elements) both schemes appear about equally complex. Also field experience shows good reliability for both schemes. Hence, where both are applicable, the choice seems to depend largely on whether one prefers to place his "eggs" in an electronic or a mechanical "basket."

The statement is made that times as high as 15 cycles in clearing faults have been measured on the directional comparison carrier relays. It would be helpful to know more specifically the conditions under which these times have been obtained.

The method of transfer trip may have advantages over the carrier blocking schemes as pointed out. Such schemes simplify the relaying circuits but require a considerable amount of electronic equipment which may not be economically justified for relaying alone. The use of the microwave channel for many other functions will make it available for relaying provided the relaying terminals coincide with the terminals for the other services.

C. C. Diemond and **D. L. Wylie:** We thank the reviewers for their comments and suggestions as well as for the questions that were raised.

The experience of the Bonneville Power Administration, with respect to frequency of 3-phase faults on the 230-kv system, is quite different than that reported by W. A. Morgan and R. W. World. A review of the record for a typical pair of long 230-kv lines

for the period November 1946 to May 1950 shows a total of 30 faults. All of these were 1-line-to-ground except one which was 2-phase-to-ground. Data were obtained from automatic oscillographs and are typical for our 230-kv system.

We can recall no more than three 230-kv 3-phase faults during the past three years. The system has been monitored during this time by automatic oscillographs which are applied to about 75 per cent of the 230-kv network and which respond to well over 90 per cent of all 230-kv faults. As previously mentioned in our paper one aim of the line performance improvement program is to reduce multiphase faults through reduction of tower footing resistances and the judicious use of overhead ground wire.

With regard to the risk of minimizing the importance of 3-phase faults, we believe that the combination of long line distance relays and phase comparison carrier will give better performance on our system than most other carrier relaying methods for well over 99 per cent of all faults which might occur. Further, the risk to system operation entailed in relying on second zone distance relays for an extremely rare low magnitude 3-phase fault is not great.

With reference to the comments of Mr. Morgan and Mr. World on the effect of the interleaved bus system on directional comparison carrier ground relay operation, mutual impedance effects remain with us in many places on the system even though the interleaved bus operation is eliminated at Coulee. Even there, with the 230-kv system solidly bussed (no interleaved scheme), mutual coupling between the 115-kv Spokane lines and the 230-kv Coulee-Spokane lines give carrier relaying difficulties similar to those previously encountered with the interleaved 230-kv scheme. Phase comparison relaying should be essentially unaffected.

J. L. Blackburn and S. L. Goldsborough have requested additional information on experience with product-type ground relays. These relays have given serious co-ordination problems on long parallel transmission lines where mutual impedance effects are significant. We agree with their comment that usually faster relaying times are possible with product-type relays. However, where mutual impedance is a problem we have not always been able to obtain these fast relaying times with product-type relays. As an example, in one case on the system where potential polarized product-type relays are used, the relay energy (that is, the product of residual current and residual potential) is essentially identical for a far end of the line fault when the relay must trip and for a near end of the line fault on the parallel circuit where the relay must not trip. If the relaying energy is unchanged between these two faults, no time difference between the two can be obtained regardless of the shape of the relay time current curve.

Carrier relaying has given slow operation, for several reasons, the following of which are believed to be the most probable:

1. Slow operation of distance elements for faults near the balance point. In considering this point, it should be remembered that the discussion in the paper refers to the old style distance relay in which the reach of the third zone distance element, which starts carrier to permit operation of the carrier relaying, is reduced for phase-to-phase faults by 15 per cent, due to the use of Y-current connections. While it is true that this 15 per cent reduction could have been eliminated since we were dispensing with out-of-step trip blocking, other considerations in addition to this one, dictated the need for changes.

2. The possible slow reset of distance elements when energized from line side potentials with its consequent continuance of a carrier blocking signal from the open terminal of the faulted line.

3. The effect on directional or product-type carrier ground relays of zero sequence mutual impedances.

4. The effect on these carrier ground relays of small residual potentials from potential devices.

We cannot agree with the comment about failure of the directional elements in the directional carrier scheme. In the case of directional comparison carrier relaying, failure of the distance relaying for a 3-phase fault could result in absence of tripping by either the carrier or distance relays. On the other hand, the use of phase-comparison carrier with distance relays gives two essentially independent relaying systems for almost 100 per cent of the faults. Three-phase faults which may not be recognized by the distance relays are usually near and of heavy magnitude. Phase comparison relays, being current operated, should respond to these near, heavy magnitude faults. Those 3-phase faults which the phase-comparison equipment may not recognize are of low magnitude and are usually located some distance out on the line. This is the region where the long-line distance relay can be set to operate to best advantage and where all three (phase) distance relays as well as the phase comparison relays must fail in order to result in a failure to trip.

In response to the general questions contained in both discussions about the value of directional comparison carrier relaying, we would like to emphasize that experience indicated that the equipment installed on the long heavily-loaded lines required extensive modification or replacement. We had the choice of using either the newer long-line distance relay directional comparison equipment or phase-comparison carrier. The latter was selected to operate in conjunction with long-line distance relays for reasons given in the paper.

While we recognize that directional comparison carrier has a definite and proper field of application in protective relaying and we expect to use the scheme in certain locations on the system, we feel that the problem of adequately relaying the long heavily-loaded BPA circuits can be better solved by use of the methods proposed in our paper.

Development of Preferred Voltage Ratings for Transformers

H. P. ST. CLAIR
FELLOW AIEE

H. M. JALONACK
MEMBER AIEE

SINCE publication in May 1949 of the Edison Electric Institute—National Electrical Manufacturers Association report on Preferred Voltage Ratings for A-C Systems and Equipment,[1] many requests have been made for further explanation of the basis for the voltage ratings and taps of both power and distribution transformers covered in Tables 9 and 10 of that report. Since it was not feasible to include all of this material in the report itself, the purpose of this paper is to describe the surveys and other studies which led to the adoption of these values.

Historical Background

As pointed out in the Foreword of the 1949 report, the first attempt at voltage standardization of transformers was a report issued by the National Electric Light Association Electrical Apparatus Committee in 1922. After trial use, this was found inadequate and further study by a joint NELA-NEMA committee culminated in the publication of the 1930 Joint Report.[2]

Again it was found after a few years' experience that the transformer ratios and taps recommended in this report were not suitable for a great many, perhaps the majority, of modern systems. For example, intermediate voltage power transformers, 23 kv to 69 kv, stepping down to 2,500 volts, 7,500 volts, and so forth, from the flat ratings of 22 kv, 33 kv, 44 kv, and 66 kv with all taps below, did not give the proper ratios for average system levels in use, such as 24 kv, 34.5 kv, 46 kv, and 69 kv. As a result, utility companies generally were not buying transformers in accordance with the 1930 report. There also were reported some cases of overvoltage complaints from power customers served at one of these transmission voltages where customer-owned transformers had been purchased in accordance with the 1930 report.

Survey Procedure to Determine Existing Practices and Requirements

The new joint EEI-NEMA Committee was set up in 1938 to revise the 1930 report. It was recognized that one of the first requirements of the job would be to find out what voltage levels and transformer ratios were being used generally for power transformer applications throughout the industry. Likewise, in the lower voltages commonly used for distribution, the necessity for revisions and extensions of the 1930 report had been recognized and work by a joint EEI-NEMA Committee on Standards for Distribution Transformers was started at about the same time.

The usual method of making a survey by questionnaire was followed, the first set of questionnaires being sent out late in 1941. Although valuable information was obtained, further study of the transformer problem indicated that additional data would be needed, particularly for the intermediate voltage classes 23 kv to 69 kv. Accordingly, a second questionnaire was circulated covering this group of system voltages and requesting information as follows:

1. Normal operating transmission voltage levels:
   a. At supply points, such as generating stations or substation sources.
   b. At average intermediate points.
   c. At outlying points, extremities of system.
2. Voltage ratings and taps on step-down transformers:
   a. On prevailing types of transformers now in use.
   b. As specified for new purchases.
3. Most frequently used tap setting or settings.
4. Voltage range on low side of distribution supply stations (ahead of feeder regulators if used):
   a. Maximum.
   b. Average.
5. Lamp voltage rating recommended to customers on system.

When the EEI-NEMA Joint Committee on Standards for Distribution Transformers was formed in 1938, it had the benefit of the very considerable amount of thought and study which had been given previously to the study of voltage ratings and voltage taps in the distribution transformer field, all of which was carefully reviewed. The ini-

Figure 1. Range of operating voltages for 23-kv systems as reported in questionnaire replies

Average level at intermediate system points indicated by "X"

Paper 50-166, recommended by the AIEE Transformers Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 15, 1950; made available for printing May 9, 1950.

H. P. St. Clair is with the American Gas and Electric Service Corporation, New York, N. Y., and H. M. Jalonack is with the General Electric Company, Pittsfield, Mass.

The authors wish to acknowledge the co-operative efforts of all of the other members of the Joint EEI-NEMA Committee on Preferred Voltage, who collaborated in this phase of the Committee's assignment. Particular acknowledgment is made of the large amount of work contributed by the late W. R. Markley and of the more recent participation on the Transformer Working Group by T. J. Brosnan.

Figure 2. Range of operating voltages for 34.5-kv systems as reported in questionnaire replies

Average level at intermediate system points indicated by "X"

tial scope of the committee work was in the field of high-voltage ratings, 2,400 to 15,000 volts, with low-voltage ratings 600 volts and below. Several reports covering these voltage classes were issued, the first in 1940 on single-phase pole-type units up to 25 kva. Later reports extended the range through 500 kva and included 3-phase as well as single-phase units.

The large amount of data and advice obtained by and made available to this Committee for an intensive and intelligent study of the distribution transformer situation included:

1. Considerable information on usage as reported by the transformer manufacturers.

2. Previous studies of distribution transformer voltages by various operating groups.

3. The substantial background knowledge of the utility members of the Joint Committee.

4. Consultation with the AIEE Subcommittee on Industrial Power Applications.

5. The advice and help through questionnaires of 130 user companies throughout the United States.

6. A final review by the Transmission and Distribution Committee of the Edison Electric Institute.

From all of this it can be said that a great deal of intensive work went into the selection of the ratings chosen and it is believed that all viewpoints were most carefully considered before the standards were established.

Figure 3. Range of operating voltages for 46-kv systems as reported in questionnaire replies

The term "distribution transformer" has been used extensively in statistical and manufacturing classifications to denote transformers for light, power, or general purpose applications in kilovolt-ampere ratings, 500 kva and smaller, regardless of voltage. However, in actual usage the classification is not that clearly defined since transformers over 500 kva may be used for distribution while transformers 500 kva and smaller may be used as substation units in power transmission. In the work of the EEI-NEMA Committee on Preferred Voltage Ratings for A-C Systems and Equipment, it was decided to handle the situation in the following way:

a. To consider as one group those ratings commonly classified as distribution transformers and manufactured in regular quantity production, specifically those 500 kva and smaller, high voltage 15,000 volts and below, low voltage 600 volts and below.

b. To consider as a separate group those transformers, 500 kva and smaller, with high voltages above 15,000 volts, also commonly called "distribution transformers." For this group it was planned to utilize high-voltage ratings and taps consistent with larger sizes for general power purposes, keeping in mind fundamental data available on transformers having low voltages of 600 volts and below.

Results of Survey—Power Transformers

The most effective summary of existing practices with respect to voltage levels, transformer ratios, and taps, and so forth, was obtained by plotting the results of the survey on a series of charts. These proved to be very helpful and will be used in this paper in describing the basis for our final conclusions.

The first basic picture was the range of operating voltage levels, shown in Figures 1 to 4 inclusive. In these figures it will be noted that the range for each company system is indicated by a vertical line, and the average voltage at intermediate points is marked by a cross on this line.

The next picture obtained from the survey covered the ratios and taps in use on existing transformers, the most frequently used taps, and the taps specified for new purchases.

In studying this information as received from questionnaire replies, it was found that many systems used transformer ratios and taps which followed early historical patterns. Except for the 46-kv class, this pattern was based on transformers with 2,300-volt secondaries or multiples thereof and primaries of 22,000, 33,000, and 66,000 volts, with $2^1/_2$-per cent taps, usually all below these values. Since a 2,300-volt secondary has long since been recognized as too low, the 2,400-and 2,500-volt secondaries were adopted, still keeping the same equivalent ratios by increasing the primary voltage ratings in proportion. For example a 33,000/2,300-volt transformer became 35,900/2,500 volts. In the 46-kv systems the basic historical ratio appeared to be 44,000/2,400 volts, giving an equivalent of 45,800/2,500 volts.

In order to summarize these results and present them in a clear, graphical form,

Figure 4 (right). Range of operating voltages for 69-kv systems as reported in questionnaire replies

Average level at intermediate system points indicated by "X"

Figure 5. Operating voltage range and transformer taps for 23-kv systems as reported in questionnaire replies

Horizontal lines represent ratios based on historical 2,300-volt secondaries

Figures 5 to 8 inclusive were prepared. It will be noted that the horizontal lines in these figures represent a given ratio which is based on the prevailing historical ratio mentioned above. For example, in Figure 6 showing 34.5-kv systems, the horizontal lines correspond to ratios which for a 2,300-volt secondary would represent primary ratings of 33,000 volts with exact $2^1/_2$-per cent taps. To cover all of the ratings reported, eight horizontal lines are included in the figure. Since these horizontal lines represent fixed ratios, the same lines can be used with equivalent primary voltages to represent transformers with other secondary ratings, such as 2,400 or 2,500 volts. This has been done as indicated on the figures, the equivalent primary voltages for 2,500-volt secondaries being given at the left side of the figure. It will be noted further that the practices of each of the reporting companies were represented on these figures by three vertical lines, the left line being the voltage range, repeated from Figures 1 to 4 inclusive. The center line shows the prevailing pattern of transformer taps now in service, while the line on the right shows the taps currently specified for new purchases. The numbers at the top of the two vertical lines indicate the actual secondary voltage rating used or specified for new purchases. From these figures it is possible to determine the complete voltage rating of the transformer. For example, company number 56 was actually using mostly 2,300-volt secondaries, and by referring to the primary voltage ratings under equivalent 2,300-volt secondary at the right side of the figure, it will be seen that these transformers have 22,000-volt primaries with four $2^1/_2$-per cent taps below. The figure 2,400 at the top of the third vertical line over company 56 indicates that new transformers are being purchased with 2,400-volt secondaries and with primary ratings of 23,000 volts. It should be noted that the secondary ratings at the top of the vertical lines have been shown only in terms of 2,300, 2,400, 2,500 volts, and so forth, even though multiples of these voltages, such as 7,200, 7,500 and so forth, actually were used. Also under each company number at the bottom of the vertical lines is indicated the approximate load of the particular system, or portion of the system, on which these transformers were used. The middle vertical line, showing existing transformer taps, also includes a designation of the most frequently used tap.

Table I. Proposed Preferred Voltage Ratings 23-Kv and 34.5-Kv Classes

Ratio	Group I, 2,500 Volts Secondary	Group II, 2,375 Volts Secondary	6-Tap, 2,500 Volts Secondary	Historical, 2,300 Volts Secondary

Determination of Voltage Ratings and Taps—Power Transformers

The basic information summarized in these four figures was used as a starting point to discuss possible standards for ratios and taps which would meet the requirements of the greatest possible number of users. In the light of the range of operating voltages and variation in transformer ratios and taps now in use, it was immediately recognized that a single standard transformer with a 10-per cent tap range would not cover all of the industry requirements in any of the four voltage classes. One suggestion for providing a greater range without going above four taps was to use larger steps. For example, four $3^1/_2$-per cent taps would increase the range to $13^1/_2$-per cent, while 4-per cent steps would increase it to 16 per cent. It was the general concensus of opinion, however, based on thorough discussion within the Committee as well as further study of questionnaire replies, that such a departure from present generally used $2^1/_2$-per cent steps would not be acceptable, first, because they would not match existing transformers from a paralleling standpoint, and, second, because the steps were considered by many to be too large. While it is undoubtedly true that the importance of exact matching of transformer ratios in parallel operation is very often overemphasized, nevertheless it was quite evident that adher-

Figure 7. Operating voltage range and transformer taps for 46-kv systems as reported in questionnaire replies

Figure 8. Operating voltage range and transformer taps for 69-kv systems as reported in questionnaire replies

Horizontal lines represent ratios based on historical 2,300-volt secondaries

ence to the traditional $2^1/_2$-per cent taps with ratios based on the actual historical voltage ratios most frequently used would enjoy the greatest acceptance and adoption by the industry.

The next step considered for obtaining in a single standard transformer the necessary tap range to meet the majority of industry requirements was to increase the number of $2^1/_2$-per cent taps above the present standard number of four. At this time the manufacturers, through their representatives on the Joint Committee, made a sincere effort to determine whether or not it would be possible to realize enough savings in the manufacturing cost of a standard widely used transformer to offset the greater inherent cost of supplying five $2^1/_2$-per cent taps or six $2^1/_2$-per cent taps, as against the adoption of two or more standard 4-tap transformers, each covering a different voltage range. Referring again to the figures, it was apparent that a 6-tap transformer would cover practically all of the system requirements reported, and that in two out of the four voltage classes a 5-tap transformer would go a long way in that direction. A choice was not required, however, as the manufacturers, after a thorough study over a considerable period of time, came up with the conclusion that the increased cost of developing and manufacturing even a 5-tap transformer, as against the present 4-tap design, could not be offset by the savings due to standardization even though such a transformer were generally adopted.

At this point, therefore, the Committee worked out, with the aid of the figures, the two groups of 4-tap transformers which appeared best suited to the requirements of the great majority of the operating companies as reported in the replies to questionnaires. These two groups differed only in the secondary voltage ratings, the primary winding and taps being the same for both. The original idea was to use a 2,500-volt secondary (or multiples thereof) for Group-I transformers, those suitable, in general, for distribution supply stations, and to use a secondary winding 5 per cent lower, or 2,375 volts, for Group II, those generally intended to take care of industrial customers requiring lower voltages than distribution systems. Group-II transformers also could be used, on a slightly overexcited basis, on systems where the transmission voltage is somewhat above the average range considered for transformers in Group I.

The reason for suggesting 2,375-volt secondaries for Group II instead of the more common 2,400-volt secondaries was to provide a full 5-per cent difference between the two groups so that the resulting ratios would match correctly on three overlapping tap positions. This feature was believed to be valuable to permit the use of both types of transformers on one system and still retain the possibility of exact parallel operation on three taps. This original proposal for each of the four voltage classes, 23 kv to 69 kv, inclusive, is illustrated in Tables I and II, in which the equivalent ratios are represented on horizontal lines. This representation shows how the two groups overlap at three points and also shows how the new proposed standard was related to the historical pattern. At that time it also was felt desirable to suggest the tap rat-

ings to be used in case a 6-tap transformer was desired by a given customer in spite of failure to include such a transformer as a standard.

Subsequent deliberation by the Committee, and reactions obtained from many users, led to the conclusion that it would be better to retain the familiar 2,400-volt secondary for the Group-II transformers and to increase the Group-I secondary to 2,520 volts, thereby retaining approximately the 5-per cent differential between the two groups. This revision was carried out, still matching historical ratios, simply by increasing the primary voltages of both groups approximately in proportion to the increase in the secondary voltage. The result of this revision is shown in Tables III and IV. The 6-tap transformer was deleted from the table at this time as it was felt that its inclusion would give a false indication of its status as a preferred standard.

In spite of the fact that the range of primary voltages and taps covered by these tables was selected with a view to giving the best coverage of existing requirements as shown in Figures 1 to 8, a subsequent circulation of the proposals among various company groups brought out sufficient data to substantiate a request for a downward adjustment in the voltage ratings of two of the classes, namely, the 46-kv and 69-kv systems. Although this differed from our first interpretation of Figures 7 and 8, it was decided to make this change, particularly since in any case there is a factor of judgment involved in selecting the best tap range for the data given in the figures. Accordingly, in Table IV the top voltage tap was removed and one additional tap added at the lower end of the range for each of these voltage classes.

While reference has been made in all of the preceding discussion to $2^1/_2$-per cent taps, it was decided rather early in the Committee's study that the tap spacings for all of these voltages should be rounded off to fairly even numbers, even though this resulted in ratios which might differ by a fraction of a per cent from the existing historical ratios. In the first place, the practical limitations in design and manufacture do not produce exact ratios without a certain allowable tolerance, and in the second place, a small discrepancy in ratio, even as high as 1 per cent, is not a real handicap for parallel operation and may even be used to advantage to offset moderate differences in transformer reactance. Keeping these considerations in mind, as well as the desirability of obtaining, if possible, a

Table VI.* Step-Down Power Transformers

Preferred Voltage Ratings

Nominal System Voltage, Volts	Transformer Voltage Designation, Kv	Step-down Power Transformers High-Voltage Rating and Tap Voltages: Group I Ratio	Group I 2,520 Volts Low Voltage	Group II Ratio	Group II 2,400 Volts Low Voltage

Notes to Table VI.

* Reproduced from Table IX, reference 1 of this paper.

** Performance characteristics should be specified on the basis of the tap voltage rating shown in bold-face type in the table.

If more than four taps are required for the high-voltage winding, it is recommended that, if possible, the tap voltages given in the table be used with additional taps above or below, using same voltage steps (for example, 900 volt steps for 34.5-kv transformers).

All voltage ratings should be full-rated kilovolt-amperes. Also, in accordance with ASA Standards C-57, the transformers are required to be capable of delivering rated output in kilovolt-amperes at 5 per cent above rated low voltage, without exceeding the specified temperature rise.

If a low-voltage rating higher than 2,520 volts is required, it is recommended that the desired low-voltage rating be chosen for use with the preferred high-voltage rating so as to secure matching overlapping ratios with the transformer having a low-voltage rating of 2,520 volts; for example, a low-voltage rating of 2,940 volts should have three matching overlapping ratios with the transformer having a low-voltage rating of 2,520 volts. If other low-voltage ratings are required, they should be selected in steps of 60 volts, that is, $2^1/_2$-per cent steps on a 2,400-volt basis.

For low-voltage ratings for transformers for use on systems with nominal voltages higher than 2,400, multiples of 126 (5,040 for 40 base voltage, and so forth) should be used for Group-I transformers and multiples of 120 (4,800 for 40 base voltage) should be used for Group-II transformers. The preferred secondary voltages for systems 20 base voltage to 120 base voltage, inclusive, are tabulated below:

Nominal System Voltage	Low-Voltage Rating			
	Group I		Group II	
	Single-Phase	Three-Phase	Single-Phase	Three-Phase
2,400	2,520	2,520	2,400	2,400
4,160	2,520/4,360Y	4,360	2,400/4,160Y	4,160
4,800	5,040	5,040	4,800	4,800
7,200	7,560	7,560	7,200†	7,200†
8,320	5,040/8,720Y	8,720	4,800/8,320Y	8,320
12,000	12,600	12,600	12,000	12,000
12,470		13,090	7,200/12,470Y†	12,470†
13,200	7,960/13,800Y	13,800	7,620/13,200Y	13,200
13,200			13,200	13,200
14,400			14,400	14,400

† For industrial applications, a preferred low-voltage rating is 6,900 or 6,900/11,950Y.

little more rather than a little less than the 10-per cent range, the Committee found that a satisfactory pattern of taps would be obtained for all voltage classes above 23 kv by basing the 10-per cent range on the even values, 24,000, 36,000, 48,000, 72,000, and so forth. This procedure resulted in steps of 600, 900, 1,200, and 1,800 volts for the tap spacings in these four voltage classes. Notwithstanding the fact that the resulting tap range in terms of the nominal voltages for these classes comes out about 10.4 per cent instead of 10 per cent, and for the 46-kv and 69-kv transformers it also exceeds 10 per cent in terms of the highest tap rating, the manufacturers agreed to provide this range in the interest of setting up a simplified, consistent pattern in these voltage classes.

No mention has been made thus far of the 27.6-kv class, which was originally omitted as somewhat of a nonstandard, or at least nonpreferred, voltage. Later consideration, however, indicated the desirability of including preferred standards for this voltage also, since it represents a considerable volume of usage even though concentrated in a few large systems. For this voltage the logical interval between taps was obviously 700 volts, corresponding to a 10-per cent range based on 28,000 volts.

Consideration also was given to voltages above 69 kv, and a considerable amount of information was brought together both from the users and manufacturers bearing on the selection of a pattern of voltage ratings and taps for these higher voltages. Obviously, at these ratings, particularly above 138 kv, the more common voltage transformations would be stepping down to intermediate transmission voltages of perhaps 23 kv and above rather than to the various distribution voltages. In spite of this, however, it was agreed by both the power system and the manufacturers' representatives that it would be highly desirable to continue the same consistent pattern as that adopted for the 23-kv to 69-kv range, extending this to all of the higher voltages, 115 kv, 138 kv, 161 kv, and 230 kv. Table V shows this extended pattern, omitting, of course, the classification into two groups.

In the final preparation of the transformers tables for publication in the Joint Report on Preferred Voltage Ratings it was decided to include only the voltage class up through 115 kv, since this might be considered a dividing line between transformers stepping down to distribution voltages and those stepping down to intermediate transmission. Although the higher voltages were omitted from the tables, the pattern of taps listed in Table V of this paper was agreed upon by both utility and manufacturers' representatives as constituting a sound basis for standards. Thus, this pattern of taps, extended to the higher voltages and approved both by the EEI and NEMA representatives, now is considered as equally standard with units having the conventional four $2^1/_2$-per cent taps, even though the tap range based on the highest tap specified is slightly in excess of 10 per cent.

In Tables I through IV the numerical ratios shown are approximate values based on the historical ratings included in these tables. In the final preparation of figures for Table 9 of the Joint Report, historical ratings were not included and the exact ratios resulting from the even pattern of taps were worked out and shown separately for each group, that is, for the 2,400-volt and 2,520-volt secondaries. As already pointed out, the overlapping taps are not exact but in all cases the deviation is relatively small, usually less than one-half per cent, and in no case in excess of three-fourths of 1 per cent. In regard to the voltage to be designated as the *transformer rating*, it is obvious that the process by which these transformer tap voltages were derived does not provide any one voltage which corresponds exactly with the nominal system voltage class for that transformer. The transformers, however, can still be referred to by the nominal voltage class designation and the matter would be of no further importance except that, from the designer's standpoint, it is necessary to designate one of the actual voltage ratings or taps on which to base his fundamental design characteristics. Since each of these transformers has five voltage connections, any one of which may be used in operation, it is obviously logical to base the transformer design upon the middle voltage and to designate this voltage as the rating at the transformer. This has been done throughout all of the transformer ratings included in Table 9 of the published Joint Report, such ratings being shown in heavy type.

As previously pointed out, in all of the tables and charts and in the final table of the report secondary voltage ratings have been given as 2,520 for Group I and 2,400 for Group II. The same tables, of course, will apply to various other standard distribution voltage ratings, and these are designated for each of the two groups in a separate table included as a footnote to Table 9 in the Report, reproduced herewith as Table VI.

Determination of Voltage Ratings and Taps—Distribution Transformers

In the following discussion reference will be made to the Joint Report on Pre-

ferred Voltage Ratings, Tables 10, 10A, and 10B, which are reproduced in this paper as Table VII A and B.

In determining the voltage ratings of distribution transformers 500 kva and smaller, 15,000 volts and below, certain factors were immediately evident:

1. The 120-volt base was well established and in general use on transformers in this classification.

2. For considerations of economy in manufacture, stocking, handling, and usage, a minimum number of alternate voltage ratings was desirable.

3. Due weight and preference should be given to the well-established primary voltages. A voltage in very small usage would not constitute the basis for standardization merely because it existed.

4. Combination units embracing several primary or secondary voltage classes would be utilized where practical.

5. The size, range, and location of the taps would have to factor the normal and permissible ratings of motor and control equipment.

6. The kilovolt-ampere ratings for each voltage combination would have to be given careful consideration in the interests of economy and because all kilovolt-ampere ratings were not needed in all voltage classes.

Referring to Table VIIA, the first column is that of primary voltages. The 2,400-volt class utilized for 2,400-volt delta systems or 4,160-volt Y systems was an obvious choice—throughout the complete kilovolt-ampere range. The usage of a 4,160-volt delta transformer was rather limited in the larger ratings but there had existed a steady demand in the smaller kilovolt-ampere ratings for this unit for connection line-to-line on a 4,160-volt system and occasionally for line-to-neutral on a 7,200-volt Y system. This unit was, therefore, included through 100 kva.

The 4,800-volt class was also in wide usage and was again an obvious choice. The necessity of units rated 2,400×4,800 volts was carefully reviewed and it was found that a great many companies either operated both systems or were in the process of changing from one system to the other. The double rating 2,400 ×4,800 volts therefore was retained.

The usage of 7,200-volt transformers for either 7,200-volt delta or 12,470-volt Y systems was sufficiently widespread to justify standardization throughout the kilovolt-ampere range. For rural work there had developed a strong demand in the small kilovolt-ampere ratings for a single-bushing transformer designed for use on a 12,470-volt/7,200-volt multigrounded system. This rating therefore was included through 25 kva.

There had been considerable utilization of 7,620-volt transformers for application on 13,200-Y volt systems. This rating therefore was included in the complete range through 500 kva and in the single-bushing grounded-Y rating through 25 kva. The application of this rated unit to existing systems operating at 7,940/13,800-volt Y level will be discussed later.
